Abstract

Imitating the best strategy from the previous period has been shown to be an important heuristic, in particular in relatively complex environments. In this experiment we test whether subjects are more likely to use imitation if they are under stress. Subjects play a repeated Cournot oligopoly. Treatments are time pressure within the task and distractions through a second task (a Stroop-task) that has to be performed as well and influences payment. We measure stress levels through salivary cortisol measurements and through measuring the heart rate. Our main findings are that time pressure and distraction can indeed raise physiological stress levels of subjects within our task. More importantly from an economic perspective, we can also observe a corresponding behavioral change that is indicative of imitation.

JEL codes: C91, C72, D74.

Keywords: stress, cortisol, heart rate, imitation, experiment.

*We would like to thank Maria Bigoni, Peter Duersch, Steffen Huck, and Burkhard Schipper as well as seminar audiences at the ESA Cologne, 2012, the TIBER workshop 2013, the HeiKaMaX workshop in 2013, and at the Universities of Innsbruck, Jena, and Nürnberg for comments. We also thank Hannes Rau for valuable research assistance and the DFG for financial support.

1 Introduction

Economic decisions are often made under stress. Obvious examples are traders on financial markets who are subject to extreme time pressure, cognitive load through multitasking, and steep financial incentives. To a lesser degree, this is true for most professions: Decisions often have to be taken under time pressure and with many distracting factors present.

There is a growing psychological literature on the effects of stress on specific aspects of decision making. Some of the key findings are that acute stress seems to impair strategic thinking (see e.g. Leder et al., 2013). Stress also seems to inhibit learning from feedback (Petzold et al., 2010; Starcke et al., 2008) and to shift learning processes from goal-directed to habitual (Schwabe et al., 2012). Taken together, stress seems to impair deliberate reasoning so that decisions are made in a more automated manner. Thus, under stress, behavioral deviations from homo oeconomicus may be even more pronounced than usual.

One way of coping with stress may be for decision makers to employ simple heuristics like imitation rather than cognitively demanding optimization. The simple heuristic of imitating the best strategy from the previous period has a lot of appeal, in particular in relatively complex environments. It has been shown theoretically to be a robust and successful heuristic in many circumstances because it is difficult to exploit by opponents (see e.g. Duersch et al. 2012). Empirically, imitation turned out to describe fairly well the behavior of many experimental subjects in complex strategic situations (see e.g. Huck et al., 1999; Offerman et al., 2002; Apesteguia et al., 2007, 2010). So the question arises whether there is more imitation under stress.

In this experiment we test whether subjects are indeed more likely to use imitation if they are under acute stress. Subjects play a repeated Cournot oligopoly. Rather than inducing stress through some external task as in most psychological studies (e.g. using the Trier Social Stress Test, Kirschbaum et al., 1993), in our experiment stress can arise endogenously in the main task. Apart from a base treatment there are two treatments that potentially raise stress levels: In treatment Time pressure subjects are fined if they do not decide within a set time interval. In treatment Distraction a second task (a Stroop-task) has to be performed concurrently inducing cognitive load. Arguably, both of these manipulations are typical of modern workplace conditions with deadlines that have to be met and distractions through email or phone calls that require immediate attention.

To check whether our manipulations work, we measure stress levels through salivary cortisol and heart rate measurements. The release of stress-related hormones supports

the adaptation process of the organism to changes and can protect the body in the short run. Under stress, cortisol for example redirects energy utilization among various organs. It simultaneously amplifies energy mobilizing mechanisms and inhibits less relevant organ functions. This helps to overcome the increased metabolic demand presented by a host of challenges. Cortisol also impacts on other important physiological systems and exerts significant effects on brain areas involved in affective and cognitive processes like declarative, episodic, and short-term memory (for a meta-analytic review see Het et al., 2005). The free fraction of cortisol, which can be measured in saliva, has been established as a biomarker of psychological stress (for a recent review see Hellhammer et al., 2009). Stress exposure also usually elicits temporary increases in heart rate and blood pressure (Kudielka et al., 2004).

Our main findings are that time pressure and distraction can indeed raise physiological stress levels of subjects within our task. More importantly from an economic perspective, we can also observe a corresponding behavioral change that is indicative of imitation. In particular, markets in our experiment become a lot more competitive under stress, a finding that is compatible with more imitation (Vega-Redondo, 1997). When looking at individual behavior, we find further direct evidence that subjects resort more to imitation when under stress. For example, subjects use significantly more often the information about others' actions and profits. Also, individual adjustments are on average more in line with imitation than with best reply behavior.

In the next section we summarize the related literature. In Section 3 we describe the details of our experiment. Section 4 reports the results and Section 5 concludes.

2 Related Literature

In this section we try to summarize the related literature from psychology and economics on stress and decision making. Stress seems to increase risk taking (Starcke et al., 2008; Putman et al., 2010; not however in von Dawans et al., 2012) as well as to have an effect, depending on gender, on the willingness to accept ambiguity (Van den Bos et al., 2009; Preston et al., 2007; Lighthall et al., 2009). Furthermore, Leder et al. (2013) find first evidence that stress may inhibit strategic thinking. In their study, stressed participants showed lower levels of strategic reasoning, probably due to less deliberate reasoning under stress. Indeed, other studies also suggest a shift from deliberate to more automated thinking styles under stress. Kassam et al. (2009), for example, report less adjustment in an

anchoring-and-adjustment task for stressed participants. Porcelli and Delgado (2009) found that the reflection bias, i.e. risk taking for losses but risk avoidance for gains (cf. Kahneman and Tversky, 1979), was more pronounced under stress.

However, from a behavioral economics point of view, the above-reviewed results regarding how stress influences decision making are limited in several ways. Most of the psychological studies of stress and decision making so far used hypothetical situations or situations with very low incentives (with the exception of von Dawans et al., 2012). This is unfortunate, as it has been shown in several studies that incentives do matter (for a review see Camerer and Hogarth, 1999). Most importantly in this respect, many decision making “anomalies” or “biases” disappear when subjects are strongly motivated by monetary incentives. The finding that stressed subjects take suboptimal decisions and learn slower from feedback in hypothetical situations might simply reflect the fact that under stress, resources are used for the more important task at hand, i.e., for coping with the stressor. It would therefore be desirable to study decision making under stressful conditions in situations where performance in the experimental task is at least as important for subjects as handling the stressor.

Previous studies investigating economic decision making under time pressure found evidence for altered behavior (Maule et al., 2000; Kocher et al., 2013; Cappelletti, 2011; Sutter et al., 2003; Kocher and Sutter, 2006; Rieskamp and Hoffrage, 2008; Ibanez et al., 2009; Reutskaja et al., 2011). Most importantly, depth of reasoning decreases under time pressure (Kocher and Sutter, 2006) and information processing is altered so that less information is searched and integrated (Rieskamp and Hoffrage, 2008). Time pressure also seems to increase cooperation in public goods games (cf. Rand et al., 2012 but also Tinghög et al., 2013).

Similarly, decision making seems to be affected by cognitive load. Cognitive load is usually induced by applying a second task that has to be worked on in parallel to the decision task. According to dual process models, this should lead to impaired deliberative processing as the deliberative system relies on scarce processing resources. Therefore, decision making should become more automatic. Indeed, Duffy and Smith (2011) (see also Allred et al., 2013) report less strategic behavior in a multi-player prisoner’s dilemma under high cognitive load compared to low cognitive load. Other studies manipulating cognitive load also report altered behavior in delay discounting tasks (Franco-Watkins et al., 2010; Hinson et al., 2003) as well as risk tasks (Benjamin et al., 2013; Hinson et al., 2002) and social games like the dictator game (Hauge et al., 2009). Yet, Cappelletti et al. (2011)

only found evidence for altered behavior in an ultimatum game under time pressure, not under cognitive load.

Both, cognitive load and time pressure are often used as stressors that can be applied at the same time as the task on which stress effects are investigated, in contrast to external stress induction protocols that have to be performed before the task of interest. Therefore, cognitive load and time pressure might be seen as more realistic stressors in an economic decision making context. Demanding cognitive tasks like the Stroop task (1935) or mental arithmetic tasks have been shown to be able to elicit a hormonal stress response (Dickerson and Kemeny, 2004). Yet, it is not known if time pressure also elicits physiological stress reactions. Therefore, we monitored heart rate and changes of the stress hormone cortisol throughout our study.

3 Experimental design

In a series of computerised experiments we studied a homogenous multi-period Cournot market with linear demand and cost. There were three symmetric firms in each market. Quantities could be chosen as integers between 0 and 100. The demand side of the market was modelled with the computer buying all supplied units according to the inverse demand function

$$p^t = \max\{100 - Q^t, 0\} \quad (1)$$

with $Q^t = \sum_{i=1}^3 q_i^t$ denoting total quantity in period t . The cost function for each seller was simply $C(q_i^t) = q_i^t$. Hence, profits were $\pi_i^t = (p^t - 1)q_i^t$.

In the stage game the symmetric Cournot Nash equilibrium for our integer strategy set is given by $q_i^N = 25$, $i \in I$, yielding a price of $p^N = 25$ and profit of $\Pi_i^N = 600$.¹ Of interest is also the symmetric Walrasian (or competitive) outcome where price equals marginal cost, $p^W = 1$, $q_i^W = (100 - 1)/3 = 33$, $i \in I$ and the profit is zero. The symmetric collusive or joint profit maximizing outcome would be at $q_i^C = 16$, $i \in I$, or $q_i^C = 17$, with a corresponding price of $p^C = 52$ or 49 and a profit of $\Pi_i^C = 816$.

The stage game was played with fixed matching for 15 periods and this was commonly known. After each market period subjects were informed about their personal profits. Additionally, they were reminded of their own quantity.

¹There is also an asymmetric equilibrium, in which one firm chooses 24 and the other two choose 25. Profits in this equilibrium are 600 and 625, respectively.

Table 1: **Theoretical benchmarks**

Outcomes	Individual quantities	Prices	Profits
Collusion	16/17	52/49	816
Cournot–Nash	25	25	600
Walrasian / Imitation	33	1	0

In round 1, all subjects had access to a profit calculator, which allowed to input hypothetical quantities for all three firms and would calculate the respective profits. At the end of rounds 1 through 14, subjects had to choose whether in the next round they would like to again use the profit calculator or whether they would receive information about the profits and quantities of the other two firms.² Obviously, the first choice would be indicative of an interest in best reply behavior while the second would provide the necessary feedback for imitation to work.³

Table 2 summarizes the three treatments of our experiment. Treatment *Base* is the standard oligopoly experiment with the feedback choice as explained in the previous paragraph. Subjects were paid according to their total profits from all rounds. Profits were denominated in ‘Taler’, the exchange rate for euro (600:1 in treatments *Base* and *Time pressure* and 1000:1 in treatment *Distraction*) was known. Additionally, subjects received a show-up fee of 5 euro.

Treatment *Time pressure* was like *Base* except that subjects had to make their quantity choices within a set decision time. In round 1 there was no time pressure. For round 2, the decision time was 40 seconds, which was calibrated to roughly 2/3 of median response time in *Base* from rounds 2 through 5. Since the response times in *Base* were decreasing throughout the experiment, we reduced the decision times by 2 seconds every period so that it was 14 seconds in the last period in order to keep the time pressure up. The screen showed a large clock counting down the seconds. There was a penalty of 300 Taler (about half of the Nash equilibrium profit) for not entering a quantity in time. If subjects failed to enter a new quantity, the quantity from the previous period was used again to calculate profits.

Treatment *Distraction* was like *Base* except that in irregular intervals subjects had to

²Bigoni (2010) and Bigoni and Fort (2013) also recorded the look-up patterns of subjects with respect to the information they acquired. In their experiments, though, subjects did not have to make an exclusive choice among the information accessed. Rather, subjects could see all information in each round.

³Strictly speaking, subjects could only infer the best response from the previous period’s price as they were not informed about the individual quantities.

Table 2: **Treatments**

Base	standard oligopoly experiment
Time pressure	from round 2: shrinking decision time 40, 38, 36, 34, . . . ,14 sec. penalty of 300 T (\sim half Nash-eq. profit) if no decision countdown prominently shown on screen
Distraction	in irregular intervals: pop-up Stroop-task, 1-2 sec. payoff: (1+ fraction correct in Stroop) (payoff from main task)

perform a Stroop-task. The task popped up on the screen and subjects had between 1-2 seconds to answer. The task (Stroop, 1935) was a multiple choice task where subjects had to name the font color of a word like “Green” or “Red” where usually the font color and the meaning of the word differed. The Stroop tasks kept popping up until the last subject of a group had entered a quantity for the oligopoly task. Subjects’ overall payoff was calculated as (1+ fraction of correct answers in the Stroop task) times the payoff from the oligopoly task.

The experiments were conducted in the experimental lab of the economics department of the University of Heidelberg. Subjects were recruited via ORSEE (Greiner, 2004) and flyers from all over the campus.

In each session either 6 or 9 subjects participated. All sessions were conducted at the same time of day (2:30 p.m.) since cortisol levels typically follow a daily cycle. The experiment was computerized using z-Tree (Fischbacher, 2007). Subjects were randomly allocated to computer terminals in the lab such that they could not infer with whom they would interact in a fixed group of three. For each treatment we had seven independent groups of subjects – making a total of $3 \times 7 \times 3 = 63$ subjects who participated in the experiments. All subjects were male and healthy students.

The average payoff was about 14 euro. Experiments lasted about 60 minutes including instruction time. Instructions (see Appendix A) were written on paper and distributed at the beginning of each session.

3.1 Physiological measures

To check whether our manipulations worked, we collected physiological measures before, during, and after the experiment. As explained above, the free fraction of cortisol, which can be measured in saliva, has been established as a biomarker of psychological stress

(Hellhammer et al., 2009). Also, a temporary increases in heart rate is usually seen as a signal of stress exposure (Kudielka et al., 2004).

- Cortisol. Saliva samples were collected at three time points throughout the experiment using Salivette collection devices (Sarsted, Nuembrecht, Germany): one at the start of the experiment (pre-stress), one after 8 rounds of the game had been played (during stress, approximately 15 minutes after stressor onset), and one after the last round (post-stress, approximately 30 minutes after stressor onset).⁴ As the cortisol reaction is relatively slow, the cortisol peak is expected between 15 and 25 minutes after stressor onset. The number of observations was 21 for treatments Base and Time pressure. For treatment Distraction only 6 observations were available for the 2nd measurement and 20 for the 3rd.⁵
- Heart rate. Heart rate was measured continuously using Polar Sport Tester RS800CX (Polar Electro, Finland). Each participant was equipped with a breast belt and a display similar to a wrist watch was placed on the table invisible for the participant. For analysis, the Polar Pro Trainer software was used. Data were aggregated into three intervals: baseline (5 min.), part 1 of the game (round 1 through 8), and part 2 of the game (rounds 9 through 15). In between part 1 and part 2 of the game, a salivary cortisol measurement took part (see above). For some subjects data were not available due to hardware failures. The number of remaining observations were 18, 17, and 13, for treatments Base, Time pressure, and Distraction, respectively.

4 Results

4.1 Physiological data

Since cortisol levels and heart rates can vary greatly between individuals, we normalize all values by dividing through the first measurement of each subject at the beginning of the experiment, before subjects learned anything about the experiment. That is, all physiological measures are shown as ratios M_t/M_1 , where $t = 2, 3$ are the 2nd and 3rd measurements,

⁴The peak of the cortisol reaction seems to be roughly 15-20 min. after stressor onset (see e.g. Pabst et al., 2013).

⁵In session 8 and 9 of treatment Distraction subjects were so slow such that round 8 (when we usually conducted the second measurement) occurred at the time at which the third measurement was taking place in the remaining sessions. We therefore take this measure as equivalent to the third measure in the other treatments (and have missing data for the second measure).

respectively. Figure 1 compares the averages of these ratios for cortisol and heart rate for the different treatments. Usually, cortisol levels decrease in the afternoon (Engert et al., 2011), the time of the experiments. In treatment Base we have a slight decrease at the third measurement. In contrast, in treatment Time pressure cortisol ratios are higher at the 2nd and 3rd measurements. The differences to treatment Base are significant (MWU-test, $p = 0.058$ and $p = 0.013$ for the second and third measurement, respectively). There are no significant differences between treatments Distraction and Base for the second measurement. However, for the third measurement, the cortisol ratio in Distraction is significantly higher than in Base (MWU-test, $p = 0.060$).

Figure 1 (bottom panel) shows the average development of heart rates. Although heart rate ratios in treatments Time pressure and Distraction are higher than in Base, the differences are not significant according to MWU-tests.

Result 1 *Time pressure and, to a lesser extent, a Stroop task seem to increase stress levels as measured by cortisol.*

4.2 Behavioral data

In the end, what is relevant for economics are the behavioral outcomes. Figure 2 shows the average (net) profits per period aggregated over all subjects in a treatment. Only profits from the oligopoly game are shown (i.e. without payments for the Stroop task and penalties for exceeding the time limit). Recall that the Nash equilibrium prediction is a profit of 600. As expected from the previous literature (Huck et al., 1999, Offerman et al., 2002, and Apesteguia et al., 2007) we find that already in treatment Base profits (average profit per round = 516.0) are lower than predicted by the Nash equilibrium (although this difference is not significant: Wilcoxon test, $p = 0.128$, two-sided, taking the average profit from each group as one independent observation). But Figure 2 shows that the profits in treatment Time pressure (351.6) and Distraction (361.4) are lower still. The differences to Base are significant according to a MWU-test ($p = 0.048$ for Time pressure vs. Base and $p = 0.025$ for Distraction vs. Base).

Result 2 *Net profits in the oligopoly game (i.e. profits without punishment in Time pressure and payments for Stroop task) in treatments Time pressure and Distraction are significantly lower than in Base.*

Figure 1: Average cortisol (top panel) and heart rate ratios (bottom panel) of subjects across treatments.

Figure 2: Average profits of subjects in the different treatments compared to the Nash equilibrium profit.

Note: Profits are net of payments for the Stroop tasks and penalties for exceeding the time limit.

4.3 More imitation under stress?

Just because the aggregate outcomes are more competitive in treatments Time pressure and Distraction one cannot immediately conclude that there is more imitation under stress. A second indication comes from the feedback choices of subjects. Recall that imitation requires knowledge about the quantity and profits of the other firms in the market. But there is a trade-off: When subjects opt to receive information on quantities and profits of others, they have to give up the option of using the profit calculator in the next round. Since the profit calculator is (for most people) essential for employing any belief based learning process, we can infer something about the learning process subjects use.

Figure 3 shows the percentage of subjects requesting the two forms of feedback, split by treatment and period. Overall it is striking how large the percentage of subjects is that request information about others' quantities and profits (blue bars). However, while in treatment Base there are about 20% of subjects using the profit calculator in the first half of the experiment, there are much fewer in the other two treatments. In fact, these differences are significant according to MWU-tests (two-sided $p = 0.017$ and $p = 0.010$ for the difference between Base and Time pressure and between Base and Distraction, respectively, taking the average from each oligopoly as one observation).

Figure 3: Feedback choice of subjects in %: Green = choice of profit calculator, blue = choice to see quantities and profits of others.

Result 3 *Subjects use significantly more often the information about others’ actions and profits in treatment Time pressure and Distraction than in treatment Base.*

A possible objection is that under time pressure subjects do not even have the time to use the profit calculator. Although this may be true to some extent in treatment Time pressure, subjects have no time pressure in Treatment Distraction. They also did not try to speed up their quantity decisions in order to be able to focus solely on the Stroop task. In fact, they took more time than in the base treatment (see Figure 4, which shows the median decision times for the different treatments).

For the remainder of the section we shall focus on individual behavior since this is the most demanding test for checking whether subjects actually use imitation. First, we simply count the number of times in which a subject chose exactly the quantity that yielded the highest profit in the previous round. We call this an “imitation instance”. Table 3 lists the percentage of all quantity choices that were imitation instances, separately for each treatment. The second row in Table 3 lists the percentage of choices that were within ± 3 of the quantity that yielded the highest profit in the previous round. A χ^2 -test shows for either measure that imitation instances are more frequent in treatment Time pressure than in Base or Distraction ($p < 0.01$ for all tests) whereas there is no significant difference between Base and Distraction.

Result 4 *The frequency of imitation instances in treatment Time pressure is significantly higher than in treatments Base and Distraction.*

Figure 4: Median decision times (in seconds) of subjects for the quantity decision

Table 3: **Imitation instances**

	Base	Time pressure	Distraction
imitation instances	10.2%	21.7%	13.3%
imitation instances ± 3	32.7%	48.4%	36.1%

Note: Periods in which subjects were forced to repeat their action due to exceeding the time limit were not counted.

We suspect that subjects often show a certain kind of inertia and adjust their quantities incompletely from their current status quo (q_i^{t-1}) towards a new goal. To check whether this new goal is more in line with a prediction derived from an imitation rule or derived from a best reply process, we estimate the following equation using a random effects GLS regression:

$$q_i^t - q_i^{t-1} = \beta_0 + \beta_1 (br_i^{t-1} - q_i^{t-1}) + \beta_2 (i^{t-1} - q_i^{t-1}) + \varepsilon, \quad (2)$$

where br_i^{t-1} denotes subject i 's best reply (i.e. reaction function) given the other firms' quantities in $t - 1$; i^{t-1} stands for "imitate the best" and denotes the quantity of the firm which had the highest profit in period $t - 1$. If all subjects strictly played a myopic best reply every period, we would have $\beta_1 = 1$ and $\beta_2 = 0$. Analogously, if all subjects strictly followed the rule "imitate the best", we would find $\beta_1 = 0$ and $\beta_2 = 1$.

Table 4: Quantity adjustments: Random effect regression

dependent variable:	Base		Time pressure		Distraction	
	coeff.	std. error	coeff.	std. error	coeff.	std. error
$q_i^t - q_i^{t-1}$						
$br_i^{t-1} - q_i^{t-1}$	0.24***	0.04	0.14**	0.06	0.18***	0.03
$i^{t-1} - q_i^{t-1}$	0.39***	0.09	0.48***	0.17	0.41***	0.06
constant	-1.16***	0.39	0.00	1.32	0.47	0.81
R^2	0.45		0.46		0.45	

Note: ***, **, * significant at 1%, 5%, 10% level; $N = 294$. Robust standard errors are clustered at the group level.

As shown in Table 4, the coefficients of both variables are highly significant in all treatments.⁶ So it seems that there is a mix of the two learning processes, which is consistent with earlier findings (see e.g. Huck et al., 1999 or Bigoni and Fort, 2013). However, there are noticeable differences across treatments with respect to the size of the coefficients. While the coefficient for the imitation process is larger in all treatments, the difference is particularly pronounced in treatment Time pressure and less so in treatment Base. As before, treatment Distraction is somewhere in between.

Result 5 *Individual adjustments are on average more in line with imitation than with best reply behavior. This tendency is more pronounced in treatment Time pressure than in Base.*

⁶Running the regression jointly for all treatments with treatment dummies and interaction terms shows that there are no significant treatment differences in the learning dynamics.

Finally, we check whether the tendency to imitate may actually be related to the stress levels of individuals. For this, we run a logit regression on the probability of an imitation instance ± 3 depending on the normalized cortisol and heart rate measurements.⁷

Table 5: Probability of imitating: Logit regression

dependent variable: imitation instance ± 3	(1)		(2)	
	coeff.	std. error	coeff.	std. error
cortisol 3rd measurement ratio	0.37*	0.19	0.27*	0.14
heart rate 2nd measurement ratio	2.87**	1.38	2.31*	1.28
constant	-3.76***	1.37	-3.23***	1.22
dummy treatment Time pressure	-		0.32	0.28
dummy treatment Distraction	-		0.03	0.32
pseudo R^2	0.02		0.02	

Note: ***, **, * significant at 1%, 5%, 10% level; $N = 661$. Robust standard errors are clustered at the group level.

Table 5 shows the result of two of those logit regressions, once with treatment dummies and once without. The treatment dummies are not significant. In both specifications higher cortisol and heart rates are associated with a higher probability to imitate, although some of the results are only weakly significant at the 10% level.

Result 6 *Individuals' probabilities to imitate are increasing with their cortisol and heart rate values.*

5 Conclusion

In this paper we have studied the question whether subjects tend to imitate others more if they are under stress. To induce stress, we used two stressors that are quite typical of economic decision making, time pressure and distraction through another task. Our experimental data supports the hypothesis that stress leads to more imitation. To be precise, what we showed is that time pressure and distraction yielded physiological reactions that are typically associated with stress, namely higher cortisol levels and, to some degree, higher heart rates. We also showed that at the same time, time pressure and distraction yielded behavior that is typical of imitation

⁷We use 3rd measurements for cortisol and 2nd measurements for heart rates since heart rates react instantly while cortisol reacts with delay (see e.g. Pabst et al., 2013). Using 3rd measurements for heart rates yields results that are actually significant at the 5% level.

What we are not able to conclude is that there are direct causal links from time pressure or distraction to stress and from stress to imitation. This is for two reasons. First, it is unclear how to define stress precisely. Some researchers *define* stress to be an increase in cortisol or other physiological measures while others define stress according to behavioral features (see e.g. Levine, 1985). Secondly, it may well be possible that time pressure and distraction influence physiological measures and at the same time increase the tendency to imitate without stress being causal for imitation. An interesting test would be to check whether the administration of cortisol by itself would increase the tendency to imitate. The evidence from other tasks seems mixed. For example, Kirschbaum et al. (1996) find that treatment-induced elevations of cortisol levels are associated with impaired declarative memory whereas the administration of cortisol is not. On the other hand, Putman et al. (2010) find that the administration of cortisol does increase risk taking behavior.

From an economist's perspective, however, it may be fully sufficient to conclude that imitation is more frequent under time pressure and distraction. Whether we call this stress or not is secondary. But the behavioral effects are clear: The tendency to imitate increases when subjects are pressed for time or when they are distracted by another task. And this in turn yields more competitive outcomes.

Appendix

A Instructions

[English translation of the German instructions, differences between treatments are indicated]

Welcome to our experiment. Please read these instructions carefully.

In this experiment we want to gather a number of biological parameters in a situation of economic decision making. Before being assigned an economic task, you will receive a heart rate monitor consisting of a breast strap and a wrist watch that you will wear for the duration of the experiment. To determine certain hormone levels, we will take saliva samples several times during the experiment. The experimenter will explain in detail the procedure when collecting a saliva sample using a salivette (i.e., a small cotton roll which you will have to chew for a short time). The experiment will take approx. 90 minutes.

Rules of the economic experiment: You will have to make several decisions on the computer. In the process, you can earn real money. But first of all, please note:

Be absolutely quiet for the whole duration of the experiment. Participants ignoring this rule cannot be paid. If you have any question, raise your hand, and someone will come over.

You will receive your payoff individually and discreetly right at the end of the experiment.

The experiment’s payoffs will be calculated in Taler (T). At the end of the experiment your payoffs will be converted into euros, with $600 \text{ T} = 1 \text{ euro}$.

The experiment comprises 15 rounds.

During the whole experiment you will be interacting with two participants in this room. These two participants will stay here over the 15 rounds. No one will learn as to who interacted with whom.

Each of you represents a firm that produces and sells a product. So there are, in addition to you, two competitors who produce and sell the same product. The production costs are 1 T per unit (for all firms). Your task is to make a decision on how many units you want to sell of your product.

The following important rule applies: The higher the total quantity produced by all three firms, the lower the market price. Above a certain quantity the price becomes zero.

The profit per unit is the difference between the price and the unit cost (1 T). Note that you will suffer a loss if the price falls below the unit cost. Your profit in this round is calculated as profit per unit multiplied with the number of units sold by you.

At the end all profits realized during the rounds will be added and paid.

Starting from the second round you will receive the following information in each round:

Your own quantity and the resulting profit of the previous round.

Moreover, you can choose between two options to receive additional information:

a) Display the quantities and profits that the two other firms realized in the previous round.

b) Use the profit calculator. There you can enter hypothetical quantities for all three firms and obtain the resulting profits of the firms.

In each round you can choose only one of the two options. But you can make your choice in each individual round.

[This paragraph for treatment Time pressure only] In the first round there is no time limit for your decision. But starting from the second round on you must make your decisions concerning the quantity and the choice of feedback option within a certain time interval. This time interval is 40 seconds in the 2nd round. It will be reduced by 2 seconds for each subsequent round, so that you will have 14 seconds in the 15th (final) round. The time interval available for each round will be displayed as a big „countdown“ on the screen. If you fail to make a decision within this interval, you must pay a 300 T fine for this round. Also, the quantity you selected in the previous round will be selected automatically for this round.

[This paragraph for treatment Distraction only] In addition to this task you must execute, starting from round 2, a color recognition task at irregular times. For this task you will be shown words whose font colors are either green, blue, black, red, or yellow. Your task is to recognize the font color and then to click the associated color field. Ignore the meaning of the word and only concentrate on the font color! You must proceed quickly because you have only 1-2 seconds per task. If you select no color at all or a wrong color, the

result of the color recognition task will be marked as wrong. Assume that the proportion of correct questions of the color recognition task is x . Then, at the end, you will get the total profits over all rounds of the first task, multiplied with $(1 + x)$. This will be your payoff for the entire experiment. For example, if you have answered 80% of the questions in the color recognition task correctly, your payoff for the experiment is:

$$(1 + 0.8) \times (\text{total profit over all rounds of the first task}).$$

To achieve an overall high payoff, you have to perform well in both tasks.

[all treatments] Everything described above applies not only to you but also to the two other firms. All three of you are reading exactly the same instructions.

Have fun!
