1 LIST OF ABBREVIATIONS

µm	micrometer
µl	microliter
AcD	axon-carrying dendrite cell
ACSF	artificial cerebrospinal fluid
AIS	axon initial segment
ank	ankyrin
ankG	ankyrin-G
aOR	adjusted Odds Ratio
AP	action potential
ASD	autism spectrum disorders
BSA	bovine serum albumin
Ca ²⁺	calcium ion
ch	chicken
ChC	Chandelier cells
CIN	cholinergic interneuron
CP	critical period
CR	calretinin
CRI	calretinin-expressing interneuron
DA	dopamine
DAB	3,3'-diaminobenzidine
dk	donkey
DLS	dorso-lateral striatum
DMS	dorso-medial striatum
DSM-V	Diagnostic and Statistical Manual of Mental Disorders 5 th Edition
DYN	dynorphin
D1R	dopamine receptor 1
D2R	dopamine receptor 2
E	embryonic day
E/I	excitation/inhibition
ENK	enkephalin
FOXP1	forkhead box protein 1

LIST OF ABBREVIATIONS

FOXP1 ^{-/-}	FOXP1 knock-out
FOXP1 ^{+/-}	FOXP1 heterozygous
FOXP1 ^{+/+}	FOXP1 wildtype
FOXP2	forkhead box protein 2
FSI	fast-spiking interneuron
fT	foetal testosterone
GABA	γ-amino butyric acid
GABA _A RAP	GABA receptor A associated protein
gp	guinea pig
GPe	globus pallidus externus
GPI	globus pallidus internus
gt	goat
h	hour/s
HDAC	histone deacetylase
HRP	horseradish peroxidase
IgG	immunoglobulin
IHC	immunohistochemistry
IF	immunofluorescence
K ⁺	potassium ion
KCl	potassium chloride
K _v	voltage-gated potassium channels
LTSI	low-threshold-spiking interneuron
MBP	myelin basic protein
min	minutes
mPFC	medial prefrontal cortex
ms	mouse
Na ⁺	sodium ion
Na _v	voltage-gated sodium channel
NeuN	neuronal nuclear marker
nm	nanometer
noR	node of Ranvier
P	postnatal day
PBS	phosphate buffered saline
pENK	proEnkephalin

LIST OF ABBREVIATIONS

PFA	paraformaldehyde
PV	parvalbumin
rb	rabbit
SSC	somatosensory cortex
sh	sheep
SNc	substantia nigra pars compacta
SNP	single nucleotide polymorphism
SNr	substantia nigra pars reticulata
SP	substance P
SPN	spiny projection neuron
STN	subthalamic nucleus
S1BF	primary somatosensory cortex barrel field
TH	tyrosine-hydroxylase
rt	rat
VGAT	vesicular GABA transporter
VGLUT	vesicular glutamate transporter
VPA	valproic acid
WB	western blot
WT	wildtype

2 INTRODUCTION

Autism (or Autism Spectrum Disorders, ASD) describes a group of developmental deficits that affect approximately 1% of the population. Since its first description by *Hans Asperger* and *Leo Kanner*, a multitude of studies have contributed to the understanding of the underlying pathomechanisms (Asperger, 1944; Kanner, 1943). Advanced gene analyses have shown that the development of ASD appears to have a strong genetic component of about 60-90%, and the association with several hundred different genes and gene variants could explain the heterogeneity of the symptoms (Sahin and Sur, 2015). A major contribution to the etiology of ASD is an aberrant frontostriatal circuitry and functional connectivity, leading to an imbalance of excitation and inhibition. Specific cellular sites that structurally contribute to ASD phenotypes remain poorly understood.

The overall goal of this work was to investigate the underlying functional and morphological changes in striatal and cortical neurons in mouse models of ASD. We aimed to contribute to the general understanding of ASD as a developmental deficit to support further investigation and the development of new therapeutic options. To this end, the focus was placed on a distinct neuronal domain, the axon initial segment, in two rodent models of ASD, of which one was a pharmacologically induced model (Valproic acid, VPA), and the other was a genetic model (FOXP1 heterogeneity, FOXP1^{+/-}).

We investigated putative changes in two ASD-relevant anatomical circuits: firstly, the dorsal striatum, which mainly controls automated motor sequences and habitual behaviors and secondly the whisker-related barrel field in primary somatosensory cortex (S1BF), which projects to the dorsal striatum (Burke et al., 2017; Burton et al., 2015). As structural and functional implications of ASD at a single neuron level remain elusive, we set out to investigate structural and functional integrity and maturation of the AIS in VPA-exposed and FOXP1^{+/-}-mice.

2.1 Autism Spectrum Disorders

Autism is a complex neurodevelopmental disorder that manifests itself in a broad spectrum of impairments in social interaction, communication, and behavior (American Psychiatric Association, 2013; Figure 1). *Elsabbagh et al.* propose a median prevalence of 62/10.000, with a range of 30-116/10.000 for all pervasive developmental disorders including all ASD phenotypes and Rett's syndrome. This indicates that 0.9-1.1% of the population are affected (Global Burden of Disease Study 2015, GBD Collaborators, 2016; Elsabbagh et al., 2012).

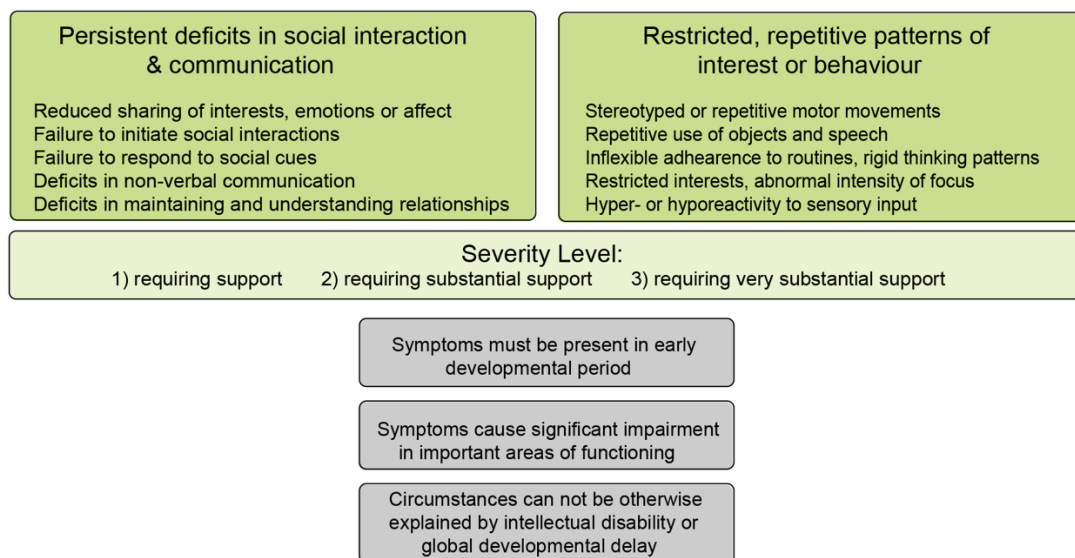

Figure 1: DSM-V criteria for the classification of ASD (299.0)

In the Diagnostic and Statistical Manual of Mental Disorders, 5th Edition (DSM-V), all autism subtypes are now united into one single diagnosis of ASD (299.0). To be diagnosed with ASD, the person must show symptoms of all categories (green), each including a severity level depending on individual support needed (American Psychiatric Association, 2013). Symptoms commonly appear during the first two years of life. If they are more severe, children are earlier diagnosed earlier with ASD than children that show with more subtle symptoms.

While autism is known to have a strong genetic component (Sahin and Sur, 2015), epigenetic changes via environmental factors must be considered when discussing ASD etiology. To date, several thousand associated genes, gene variants, copy number variations, single nucleotide polymorphisms or variable number of tandem repeats have been identified to increase autism susceptibility (Xu et al., 2012). These are roughly grouped into causal genes or 'syndromic

autism-related genes' that lead to syndromes including autistic features such as Fragile-X or Rett's syndrome (Clifford et al., 2007), and 'non-syndromic autism-related genes', which are mostly susceptibility genes (Dykens et al., 2004; Wassink et al., 2004). The most enriched pathways found in those genome-wide studies include genes for axon guidance, synaptic formation and transmission, neuronal signaling, ion channel function, and a form of synaptic plasticity termed long-term potentiation (Chang et al., 2015; Geschwind, 2011). FOXP1, which is discussed in this thesis, is considered as a syndromic gene although copy number variation related evidence exists (Stessman et al., 2017).

Regardless of the etiology, imbalance of excitation, inhibition and altered synaptic strength seem to be the favored hypotheses regarding a common denominator underlying ASD (Goncalves et al., 2017; Rubenstein and Merzenich, 2003; Yizhar et al., 2011). Abnormal synaptic homeostasis represents a risk factor as well (Bourgeron, 2009). This hypothesis is supported by findings of *Fang and colleagues*, that increasing numbers of excitatory neurons in layer II/III of the neocortex cause autistic phenotypes (Fang et al., 2014). Neuroanatomical changes to neuronal and synaptic infrastructure appear to be region-dependent (Goncalves et al., 2017).

The prevalence of patients diagnosed with ASD shows a strong bias towards males, with ratios of approximately 4:1 (male/female) for all autism spectrum disorders, whereas In Aspergers' syndrome, this ratio extends up to 10:1 towards males (Fombonne, 2012).

Genetic, endocrine and neurodevelopmental effects have to be considered as well as comorbid psychopathologies and diagnostical difficulties when trying to find an explanation for this bias (Kirkovski et al., 2013). For example, common endocrine theories speculate that increased foetal testosterone (fT) levels during the embryonic period could be directly correlated to autistic traits (Auyeung et al., 2009). Elevated fT levels show an inverse correlation to eye contact and vocabulary development in early childhood (Baron-Cohen et al., 2011).

The fact that females often require a greater etiologic load to manifest typical phenotypes led to speculation of protective mechanisms of the female sex

(Robinson et al., 2013). From all areas so far investigated, social interaction seems to be the most sensitive domain to be affected in a sex-specific manner (Jeon et al., 2018). Decreasing male/female ratios (down to 3:1) observed during the past years could be attributed to increased diagnosis and understanding of ASD presentation in females (Jensen et al., 2014). As females tend to express symptoms differently than males, less obvious signs of social impairment and altered presentation could therefore camouflage clinical symptoms and complicate adequate diagnostics (Kirkovski et al., 2013; Wiggins et al., 2014).

2.2 The FOXP1 transcription factor and its role in ASD

Transcription factors such as the forkhead box transcription factors 1 and 2 (FOXP1; FOXP2) control gene expression patterns that are crucial for proper brain development (Ayhan and Konopka, 2019). Multiple mutations of FOXP1 and FOXP2 have been linked to cognitive disorders such as ASD, Intellectual Disability and Huntington's Disease (Bowers and Konopka, 2012; Siper et al., 2017). Both FOXP1 and FOXP2 are close relatives, showing 64% total protein sequence identity and 89% identity in the forkhead domain (Bacon and Rappold, 2012). Although they seem very similar, mutations in these genes show distinct effects and characteristic phenotypes.

Target genes of FOXP2 control mostly language and fine motor control (Lepp et al., 2013). Symptoms of FOXP2 mutation include the impairment of expressive, receptive, comprehensive as well as written language, and numerous studies implicate that it is causative for inherited language disorder (Lai et al., 2001).

FOXP1 target genes are not restricted to language but control global cognitive development and gross motor function (Anderson et al., 2020; Co et al., 2020). The spectrum of symptoms following mutations includes broader neurodevelopmental deficits, such as motor and speech delay, social withdrawal, reduced anxiety, learning and memory deficits, and other key

features of ASD (Bowers and Konopka, 2012). FOXP1 knockout mice (FOXP1^{-/-}) stand out by showing restrictive and repetitive patterns of behavioral output, learning and memory deficits, impairments in social interaction, and reduced anxiety (Table 10). Those symptoms could be correlated to neuroanatomical malformations. FOXP1^{-/-} mice showed a significant reduction of the striatal area, with enlargement in lateral ventricles (Bacon et al., 2015). Surface deformation of the basal ganglia could also be found in boys diagnosed with ASD, associating those anatomical changes with ASD-typical features (Qiu et al., 2010).

Expression of FOXP1 and FOXP2 appears earliest at embryonic day 12.5 (E12.5) and persists into adulthood. The highest levels of FOXP1 and FOXP2 mRNA and protein expression are found in the developing and mature basal ganglia except for the globus pallidus (GP). The combination of *in situ* hybridization and immunohistochemistry revealed the presence of FOXP1 in projection neurons, but not in interneurons in the striatum of adult mice (Precious et al., 2016; Tamura et al., 2004). The expression of FOXP1 and FOXP2 in striatal spiny projection neurons (SPN) is differential and therefore aids the study of their distinct roles in circuit function. Over two-thirds of FOXP2 positive neurons co-expressed dopamine D1 receptor (D1R) mRNA and only 21-26% co-expressed dopamine D2 receptor (D2R). This might implicate a stronger correlation of FOXP2 to the direct pathway. FOXP1 positive neurons co-expressed D1R and D2R mRNA almost equally with no preference towards either of the pathways (Fong et al., 2018).

Apart from the basal ganglia, FOXP1 is expressed throughout layers III-V of the neocortex, the CA1 region of the hippocampus, and the thalamus (Co et al., 2020). Contrary to FOXP2, which is found in the deepest layer of the cortex, layer VI, and the cerebellum, FOXP1 expression is absent in rodent and only slightly expressed in human Purkinje cells of the cerebellum (Ferland et al., 2003; Hisaoka et al., 2010).

As implicated before, FOXP1 expression seems to play an important role in early striatal and cortical development. FOXP1^{+/-} cortical neurons showed delayed migration and altered dendritic morphology (Li et al., 2018) and FOXP1^{-/-} caused loss of striatal SPN *in vitro* (Precious et al., 2016).

In this thesis, one aim was to investigate structural changes in SPN due to FOXP1 heterogeneity in order to find possible anatomical correlations to the autistic phenotype. The influence of FOXP1 expression for cortex and basal ganglia development makes this model suitable to investigate changes in both areas. Similarities between behavioral and morphological changes between the rodent model and humans enable us to enhance our understanding of the underlying pathomechanisms of ASD.

2.3 The VPA model of ASD

VPA is an anticonvulsant drug used in the treatment of epilepsy to control absence seizures, grand-mal, and partial seizures. It is also commonly used as a mood-stabilizer in bipolar disorder and therapy-resistant migraine (DGBS e.V., 2019; Diener et al., 2018; Elger et al., 2017). At the same time, VPA is highly teratogenic (Meador et al., 2008; Weston et al., 2016). The pharmacological mechanisms of action and their effects that cause autistic-like behaviors both in humans and animals are not yet fully understood.

For the past 40 years, numerous studies have contributed to collecting evidence of its teratogenicity (Brown et al., 1980; Tanoshima et al., 2015). The European Medicines Agency's Pharmacovigilance Risk Assessment Committee only recently agreed on strengthening current restrictions on VPA usage during pregnancy, because even though previous recommendations and the current status of research indicated significant issues, many women of childbearing age are still being prescribed VPA (European Medicines Agency, 2018).

Children exposed to VPA *in utero* show various congenital malformations including a 20 times higher incidence for neuronal tube defects such as spina bifida (Alsdorf and Wyszynski, 2005), cleft palate (Jackson et al., 2016), atrial septum defects (Jentink et al., 2010), and specific minor facial features, characterized as the fetal valproate syndrome (Guveli et al., 2017), as well as psychomotor delays (DiLiberti et al., 1984; Lammer et al., 1987; Stadelmaier et al., 2017). Other teratogenic effects of VPA, such as significantly lower IQ

scores in early childhood, appear to be dose-dependent (Meador et al., 2009; Weston et al., 2016). Above all, there is a significantly increased risk of developing childhood autism and ASD (Christensen et al., 2013). The prevalence of neurodevelopmental disorders including ASD in children exposed to VPA monotherapy is 12% (adjusted Odds Ratio (aOR) 6), with VPA polytherapy at 15% (aOR 10) compared to control children that show a total prevalence of 1.87% (Bromley et al., 2013).

In utero exposure of VPA has similar effects in rodent models (Nicolini and Fahnestock, 2018; Rouillet et al., 2013). The fact that rodents mirror typical behavioral and cognitive features of humans with ASD has helped to establish *in utero* exposure of VPA as a common model of ASD. Previous studies showed that VPA exposure causes many of the symptoms that are set to define ASD in the DSM-V (Diagnostic and Statistical Manual of Mental Disorders, 5th Edition; American Psychiatric Association, 2013; Figure 1). Exposed rodents show a decreased number of social explorations and interactions as well as altered play behavior (Kataoka et al., 2013; Markram et al., 2008; Moldrich et al., 2013; Schneider and Przewłocki, 2005). Furthermore, they show a decreased number of ultrasonic pup vocalizations, which implicate difficulties in social communication (Gandal et al., 2010; Moldrich et al., 2013). Repetitive and stereotyped patterns of activity such as repetitive grooming or digging could be reproduced in a multitude of studies using the VPA model (Gandal et al., 2010; Markram et al., 2008; Mehta et al., 2011; Moldrich et al., 2013; Schneider et al., 2008; Schneider et al., 2007).

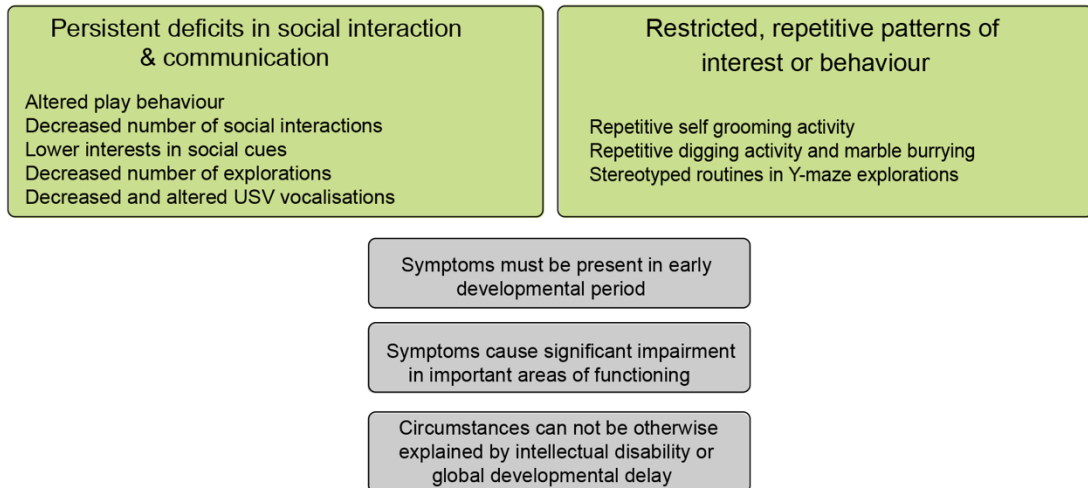

Figure 2: Core behaviors in VPA exposed rodent models based on the DSM-V manual
Core behavior and phenotypes that are seen in rodent models of ASD, according to DSM-V (Figure 1).

Contrary to the general population of ASD patients showing a strong bias towards males with a general ratio of 4:1 (male/female), the effects were not replicated in VPA models (Fombonne, 2012). In humans as well as in animals, a 1:1 sex ratio was seen after exposure to VPA (Rasalam et al., 2005). However, differences in behavior and neuroanatomical changes could still be detected between both sexes. VPA exposure leads to increased sniffing behavior in males, but not females, during social interaction tests (Kataoka et al., 2013).

2.3.1 Mechanisms of action

One possible mechanism of action of VPA is the elevation of regional gamma-aminobutyric acid (GABA) levels by increasing its synthesis and inhibiting its metabolism via GABA transaminase (Owens and Nemeroff, 2003). Impaired murine inhibitory neurotransmission mediated by GABA can lead to seizures, whereas the elevation of GABA levels has an anticonvulsant effect (Löscher, 1989). These effects appear to be region-specific, as the application of VPA showed a significant increase in cortical GABA and striatal glutamate levels (Chapman et al., 1982), but could not be reproduced in other brain areas such as the hypothalamus (Baldino and Geller, 1981). Providing evidence to support the hypothesis that autism is the result of imbalanced glutamatergic and

GABAergic neuronal differentiation and disturbed postsynaptic maturation, *Iijima et al.* showed that the number of excitatory glutamatergic synapses increases, whereas the number of inhibitory GABAergic synapses decreases in cultured neocortical neurons exposed to VPA. Additionally, murine GABAergic neurons showed a retardation of axonal growth (Iijima et al., 2016; Kim et al., 2013).

While VPA exposure did not affect the formation of the vesicular glutamate transporter 1& 2 (VGLUT 1& 2), the vesicular GABA transporter (VGAT) was decreased as well as the number of VGAT positive synapses (Kumamaru et al., 2014). Several brain regions, such as the striatum, displayed reduced levels of glutamic acid decarboxylase (GAD65 and GAD67), markers for GABA neurons, after VPA exposure (Wei et al., 2016).

Deregulation of gene expression has emerged in the context of the etiology of other neuropsychiatric disorders such as schizophrenia (Tang et al., 2011), Huntington's disease (Lee et al., 2013) and ASD (Sun et al., 2016). VPA inhibits histone deacetylase (HDAC) activity, causing transient hyperacetylation of H3 and H4 histones immediately after exposure (Kataoka et al., 2013). Corresponding to those findings, *in utero* exposure to Valpromide, a VPA analogue lacking HDAC inhibitory activity, failed to evoke any changes at behavioral, histological or biochemical levels (Moldrich et al., 2013). Hence, the influence of VPA at the level of gene transcription seems to be one of the reasons why postnatal social behaviors are affected (Kawanai et al., 2016).

Another possible explanation of VPA's teratogenic effects might result from the substance serving as a non-competitive binding partner to folate receptors, resulting in folate-deficient conditions in pregnant women. Folate-deficiency is discussed as the cause of several congenital defects (Fathe et al., 2014). It has been shown that the intake of folic acid during pregnancy may reduce the risk of children developing ASD (Schmidt et al., 2012). Folate is critical for neural tube closure that takes place around E12.5 in rodents (Rodier et al., 1996). This hypothesis is supported by the fact that the time of VPA exposure is critical to evoke postnatal effects. Rodents appeared to be most sensitive at E12.5,

exposure at earlier (E9) or later (E14.5) time points failed to cause similar effects (Kataoka et al., 2013).

2.3.2 Neuroanatomical correlations

Hallmarks of neuroanatomical alterations after the influence of VPA include changes in neuron number and packing density or volume in various regions of the mammalian brain (Edalatmanesh et al., 2013; Kataoka et al., 2013). Daily application of high doses (720 mg/kg bw) of VPA during pregnancy causes decreased total cortical and brainstem volumes in rats, which could later be correlated with learning deficits (Frisch et al., 2009). Enhanced short- and long-term synaptic plasticity, induced by elevated long-term potentiation (LTP) in the medial prefrontal cortex (mPFC), consolidating fear memories was shown to contribute to increased anxiety (Sui and Chen, 2012).

Significant reduction in the number of cells in layer II/III and V of the mPFC and the somatosensory cortex (SSC) are presumably due to the induction of an apoptotic-like cell death that appears 24 h after the application of VPA. This is followed by reduced proliferation and migration of newly born neurons (Kataoka et al., 2013). This effect seems to be sex dependent as the number of neurons in SSC of female mice remains unchanged, underlining the argument that morphological abnormalities in the SSC might be involved in the development of the sex-dependent ASD symptoms (Hara et al., 2012).

Whole cell patch-clamp recordings in layer V of rat SSC revealed several neuroanatomical changes after VPA exposure, leading to a decrease in the intrinsic excitability of that network (Rinaldi et al., 2008). Although there is a significant increase in connection probability and direct connections between neighboring cells, the strength of those connections weakens. Ultimately, the current required to reach the action potential (AP) threshold increases, which makes AP firing less probable (Rinaldi et al., 2008).

Basket cells and Chandelier cells (ChC) are two types of parvalbumin (PV) positive neurons that critically regulate the cortical excitation/inhibition (E/I) balance (Ferguson and Gao, 2018). These fast-spiking GABAergic interneurons modulate the activity of nearby neurons by either contacting the soma or proximal dendrites (basket cells) or forming inhibitory synaptic complexes

specifically at the AIS (ChC) (Kawaguchi and Kubota, 1997; Somogyi et al., 1982; Figure 3).

If the main effect of ChC at the AIS is mainly excitatory or inhibitory is still a matter of discussion (Woodruff et al., 2010; Woodruff et al., 2011), but a critical role in maintaining a physiological E/I balance in the neuronal network is very likely. Unsurprisingly, abnormal ChC development and dysfunction have been implicated in the underlying pathomechanisms of neuropsychological diseases such as ASD, schizophrenia, and epilepsy (Lewis et al., 2005; Wang et al., 2016).

Gogolla et al. reported a decrease of PV neurons and therefore decrease in inhibition in the parietal and occipital cortex after VPA exposure. The fact that this PV cell reduction was seen asymmetrically between both hemispheres could contribute to dysbalanced neuronal circuits (Gogolla et al., 2009). Interestingly, those effects could not be reproduced by others, neither in mPFC, SSC or the auditory cortex (Anomal et al., 2015; Lauber et al., 2016). Although there seems to be a disagreement whether or not changes to PV cell numbers in the cortex do appear, a 15% reduction of PV cells in the striatum was observed recently (Lauber et al., 2016). VPA exposure also caused aberrations of the striosomal compartment and of corticostriatal pathways as well as fewer putative corticostriosomal synapses of striosomal neurons (Kuo and Liu, 2017). Decreased proEnkephalin (pENK) mRNA levels measured in the dorsal striatum might be an indicator of overall increased activity in the enkephalinergic system, which could contribute to increased anxiety, one of the key features of ASD (Schneider et al., 2007).

2.4 The axon initial segment

The AIS constitutes the site of AP generation in neurons and thus plays an important role in the regulation of cellular excitability (Kole and Stuart, 2012; Figure 3). The position of the AIS in relation to the soma and dendrites is characteristic for different cell types and uniquely reflects the physiology and function of the cell (Häusser et al., 1995; Martina et al., 2000; Thome et al., 2014). The ability to maintain plasticity during development and in adulthood

determines the AIS as a new site for dynamic regulation of neuronal circuit function (Grubb and Burrone, 2010; Gullledge and Bravo, 2016; Jamann et al., 2021; Kuba, 2010; Wefelmeyer et al., 2015).

Figure 3: Cellular localization and function of the AIS.

A: The axon initial segment (AIS, green) is an unmyelinated region located at the proximal axon, regardless of axon onset (somatic/ dendritic). PV-positive interneurons (ChC) form GABAergic synapses along the AIS. **B:** Synaptic input (light blue) is received and integrated along the somatodendritic domain. Upon reaching the required threshold, an AP is initiated at the distal end of the AIS. APs are propagated along the axon. In myelinated axons, this propagation relies on saltatory conduction (dark blue arrows) from one node of Ranvier (noR) to the next, which increases conduction velocity. Ultimately, neurotransmitters are released at axon terminals.

In the context of ASD, very little is known so far about changes in structure and function of the AIS. In a recent study utilizing a mouse model of Angelman's syndrome, the authors unveiled significant changes of AIS morphology and intrinsic membrane properties in CA1 hippocampal neurons (Kaphzan et al., 2011). However, despite the intriguing findings of this study, surprisingly little data has been collected regarding putative ASD-driven effects on AIS biology, ultimately prompting the aims of the current thesis (see section 2.7– Objectives).

2.4.1 Molecular composition of the AIS

Specialized membrane scaffolding proteins and cytoskeletal components, particularly proteins of the Ankyrin family, constitute the backbones of the AIS. Ankyrins are membrane adaptor proteins that help to target other proteins such as ion channels to plasma membranes (Rasband, 2010; Figure 4).

Figure 4: Molecular structure of the AIS

The membrane scaffolding proteins Ankyrin G and β IV-spectrin anchor various ion channels on the surface to the cytoskeleton of the axon. For more details, please refer to section 2.4.1. Modified after (Engelhardt et al., 2019).

AnkG is part of the family of ankyrin proteins, together with Ankyrin-R and Ankyrin-B, encoded by the three genes ANK1 (ankR), ANK2 (ankB) and ANK3 (ankG) (Mohler et al., 2002). From its three spliced isoforms, the two isoforms of ankG, with a molecular weight of 270kDa and 480kDa, are involved in clustering transmembrane proteins such as voltage-gated sodium (Na_V) (Akin et al., 2015; Zhou et al., 1998) and potassium channels (K_V) (Pan et al., 2006).

By binding to β IV-spectrin, which in turn links to the actin cytoskeleton, ion channels are ultimately anchored at the AIS (Fréal et al., 2016; Pan et al., 2006; Figure 4). Apart from ion channels, ankG links the cell adhesion molecules (CAMs) Neurofascin-186 kDa (NF-186) and neuron-glia related CAM (NrCAM) to axonal microtubules. These help to assemble the specialized brevican-containing extracellular matrix (Hedstrom et al., 2007). β IV-spectrin on the other hand connects to the actin cytoskeleton at the AIS and nodes of Ranvier (noR) (Yang et al., 2007). The assembly of ankG at the AIS and noR precedes all other necessary components. It is assumed that other parts of the AIS as well as the extracellular matrix fail to co-localize in the absence of ankG (Bennett and Chen, 2001; Hedstrom et al., 2007; Jenkins and Bennett, 2001).

Deficiency or malfunction of ankG disrupts AIS composition and function, thus demonstrating that ankG is crucial for AIS assembly; this has been shown both *in vivo* and *in vitro* (Hedstrom et al., 2007; Jenkins et al., 2015; Kordeli et al., 1995; Letierrier et al., 2015). Mutant mice with cerebellar ankG knock-down suffered from ataxia as a consequence of disrupted AP initiation and rapid, repetitive firing at the AIS (Zhou et al., 1998).

In addition to its axonal role, the 480kDa ankG isoform plays an important role in stabilizing GABAergic synapses at the somatodendritic domain (Tseng et al., 2015). Abolishing the interaction between ankG and the GABA_A receptor-associated protein (GABA_ARAP) in a knock-in mouse model did not only cause a reduction in the number of inhibitory synapses at the AIS and somatodendritic domain, but also led to hyperexcitable pyramidal neurons and therefore disrupted network synchronization (Nelson et al., 2018).

Apart from its role as a scaffolding protein for AIS assembly, ankG plays an important role in maintaining neuronal polarity and functions as a diffusion barrier (Hedstrom et al., 2008; Sobotzik et al., 2009; Zhang et al., 2019). In the absence of ankG, neurons lose their polarity and axons start to acquire cytoplasmatic and membrane properties typical of dendrites (Hedstrom et al., 2008). Dendritic features, such as spines and postsynaptic densities of excitatory spines were observed *in vitro* (Hedstrom et al., 2008) and *in vivo* (Sobotzik et al., 2009) after the depletion of ankG.

Clinical implications of elevated susceptibility for mental disorders in relation to ankyrin have recently been noted (Iqbal et al., 2013). Increased anxiety, one of the key features of ASD, has been observed in ANK3 knockout mice (van der Werf et al., 2017).

Several studies correlating gene polymorphisms and ANK3 mutations to families with a strong association to ASD implicate a shared molecular pathophysiology between several mental disorders (Bi et al., 2012; Kloth et al., 2017). Furthermore, mutations in ANK3 have been linked to several mental disorders such as bipolar disorder (Schulze et al., 2009; Zhu et al., 2017), schizophrenia (Harrison, 2016; Prata et al., 2019) and ASD (Bi et al., 2012).

2.4.2 β IV-spectrin

As mentioned before, ankG binds to β IV-spectrin, which then connects to the actin cytoskeleton of the axon (Figure 4). Multiple cross-links between those proteins contribute to maintain the highly stable complex that builds the scaffold of the AIS and participates in ion channel clustering (Berghs et al., 2000). β IV-spectrin-null neurons fail to cluster voltage-gated sodium channels and ankG (Komada and Soriano, 2002) and disrupted AP generation due to Nav dysfunction leads to quivering and motor neuropathies in mutant mice (Parkinson et al., 2001).

Less profound effects following loss of β IV-spectrin compared to loss of ankG indicate ankG as the main scaffolding protein (Hedstrom et al., 2007; Yang et al., 2007). Nevertheless, β IV-spectrin plays an important role in regulating nodal structural integrity and the molecular organization of the AIS (Yang et al., 2004). This actin/spectrin complex is periodically organized: actin forms rings that are evenly spaced with a distance from 180-190 nm along the axon in cultures rat hippocampal neurons and peripheral nerves (D'Este et al., 2016; Xu et al., 2013), 180 nm in retinal ganglion cells (Schlüter et al., 2019), and slightly less (170 nm) in axons of avian nucleus magnocellularis (Akter et al., 2020). Spectrin tetramers, with a length of 190 nm function as spacers between actin rings, thus providing elasticity and flexibility to the cytoskeleton while maintaining a certain degree of stability (Leterrier et al., 2015; Unsain et al., 2018; Zhang and

Rasband, 2016). Furthermore, Nav channels, NF-186 and ankG seem to be organized in the same periodic arrangement (Leterrier et al., 2015).

2.4.3 Ion channels and action potential generation at the AIS

Voltage-gated sodium channels are the structural basis for AP generation at the AIS (Figure 5). The isoforms Nav1.1, Nav1.2, and Nav1.6 are enriched at the AIS. While most of the cortical excitatory neurons express Nav1.2 and Nav1.6, others, including inhibitory neurons, exchange Nav1.2 for Nav1.1 (Lorincz and Nusser, 2008). Distinct configuration of ion channel properties, therefore, seems to distinguish between several cell types present in the nervous system (Yoshimura and Rasband, 2014).

Nav1.6 is the primary voltage-gated ion channel involved in AP initiation as they activate more rapidly and at lower thresholds (Colbert and Pan, 2002; Hu et al., 2009; Katz et al., 2018; Rush et al., 2005; Van Wart et al., 2007). The maximum Na⁺ current is observed at the distal AIS, approximately 50 μm (30-70 μm) away from the soma, which happens to be the site of the maximum Nav1.6 channel density (Hu et al., 2009). The fact that these channels often localize towards the distal end of the AIS, isolating them from the capacitive load of the soma, underlines the assumption that they are critical for AP generation rather than backpropagation (Baranauskas et al., 2013; Hu et al., 2009; Kole and Brette, 2018; Lorincz and Nusser, 2008). This task falls to Nav1.2 channels that have been reported to be accumulated towards the proximal end, closer to the somatodendritic domain (Hu et al., 2009; Figure 5).

Figure 5: Ion channel distribution at the AIS

A: In interneurons (IN), Na_v 1.1 channels (dark blue) accumulate at the proximal AIS. Na_v 1.6 (light blue) and K_v 1.x (orange) are distributed uniformly. **B:** In pyramidal neurons (PNs) of cortical layer V, Na_v 1.2 replaces Na_v 1.1. **C:** In PNs of cortical layer II/III, Na_v 1.6 accumulates at the distal AIS. K_v 7.x and K_v 1.x channels are expressed additionally (green: AIS). Modified after (Gutzmann, 2015).

Voltage-gated potassium (K^+) channels (K_v) localized at the AIS play a crucial role for membrane potential repolarization during an AP. They allow a prompt influx of potassium ions in order to repolarize membrane potential and directly counteract the depolarizing effect of Na_v channels during an AP (Doyle 1998). They are active at resting potential and inactivate with slow subthreshold potentials. The most common isoforms expressed at the AIS in the cortex are K_v 1.1, K_v 1.2, K_v 7.2, and K_v 7.3 (Goldberg et al., 2008; Inda et al., 2006; Kole et

al., 2007; Lorincz and Nusser, 2008). K_v1 -type channels can be found in both pyramidal neurons and interneurons (Goldberg et al., 2008).

Patch-clamp recordings showed that pyramidal neurons mostly express $K_v1.x$ channels with the ability to be activated at a low threshold and mediating a fast-activating, yet slowly inactivating outward potassium current. The $K_v1.x$ mediated current counterbalances depolarization and has a big influence on AP waveform and repetitive firing (Shu et al., 2007). $K_v1.x$ modify the AP waveform by modulating AP width, which ultimately leads to altered neurotransmitter release at axon terminals: inactivation of $K_v1.x$ channels through slow subthreshold depolarization led to an increase of AP width in cortical pyramidal neurons of layer V (Kole et al., 2007). Likewise, blockage of $K_v1.2$ channels in acute brain slices with a selective blocker led to an increase in spike duration (Shu 2007). Each neuron type has its unique distribution pattern of potassium channels. Purkinje cells completely lack K_v1 channels, mitral cells and retinal ganglion cells only express $K_v1.2$ channels. This could contribute to the unique firing pattern of different neuronal populations (Van Wart et al., 2007).

$K_v7.2$ and $K_v7.3$ channels are enriched at the AIS and noR and preferentially expressed in a gradient towards the distal part of the AIS (Kole and Stuart, 2012; Pan et al., 2006; Figure 5). They mediate the “M-current” (M= muscarine), a slow non-inactivating current that activates just below AP threshold (Halliwell and Adams, 1982). Generally, K_v7 channels are attributed to raising the AP threshold and altering the resting membrane potential and thus reduce neuronal excitability and repetitive firing. If K_v7 channels are blocked, spike frequency increases and repetitive firing is promoted (Aiken et al., 1995). They also contribute to stabilizing resting membrane potential, which is crucial to enhance Na_v channel availability. Ultimately, this leads to an increase in the AP amplitude. In contrast to K_v1 channels, K_v7 channels adapt to firing frequency (Petersen et al., 2017). In fact, heterozygous mutations of K_v7 channels (encoded by the *KCNQ2* gene) have been associated with autistic features such as hyperactivity, repetitive behavior, and reduced sociability in mice (Kim et al., 2019). Interestingly, single-cell RNA sequencing revealed, that homozygous knockdown of *FOXP1* in D2 SPN of the striatum causes the downregulation of

two important potassium currents, inwardly rectifying and leak current. This ultimately results in higher intrinsic excitability of exclusively D2 SPN and could provide another clue for alterations of neuronal function in ASD (Araujo et al., 2015; Khandelwal et al., 2021).

Axial current follows the basic principle of Ohm's law: The voltage gradient between the soma and the AIS is dependent on input current and axial coupling resistance, which in turn is dependent on the geometry of the AIS (Kole and Brette, 2018). Following those principles, there happens to be a unique optimal position and constitution of the AIS for every neuron in relation to its morphology, constituting the compromise between a minimum threshold current and isolation from the somatic load (Goethals and Brette, 2020). According to theoretical models, the following baseline structure/function relation for the AIS have been postulated: The longer and more distally located the AIS is, the more excitable the neuron is, as it becomes easier for Na^+ and K^+ conductance to overcome the electrical load of the soma. This constitution becomes preferable for large neurons. In comparison, small neurons prefer more proximal located AIS of intermediate length to be more excitable (Goethals and Brette, 2020; Gullledge and Bravo, 2016; Kole and Brette, 2018).

Interestingly, a close functional relationship between the somatodendritic domain and the axon has been shown experimentally and theoretically (Goethals and Brette, 2020; Hamada et al., 2016). In this context, the current that is required to reach AP threshold is higher when the diameter of the apical dendrite is larger, and this relation is scaled (Kole and Brette, 2018). Consequently, cells with thin axons show reduced current to threshold and need fewer sodium channels to initiate AP generation. The ability to adapt AIS to variable dendritic loads ensures the generation of uniform somatic APs (Hamada et al., 2016; Figure 6).

Figure 6: Plasticity of the AIS

A: Large neurons have a longer AIS, more distally located, so Na^+ and K^+ conductance can overcome the electrical load of the soma more easily. **B:** This is different to small neurons, that have AIS of intermediate length that are located more proximal to increase excitability. **C:** Neurons with large axonal diameter show high current to threshold, cells need a longer AIS with more sodium channels for AP generation. **D:** Neurons with small axonal diameter, however, need fewer channels and a shorter AIS. The ability of the AIS to adapt to variably dendritic loads helps to ensure uniform somatic AP generation.

2.4.4 AIS plasticity

In cortical neurons, AIS first appear around E14.5 (Gutzmann et al., 2014). During the development of pyramidal cells in the visual cortex, the AIS assembles and then gradually increases its length until the onset of sensory input changes network state, which ultimately results in AIS shortening (Gutzmann et al., 2014; Schlüter et al., 2017; Figure 7A). Maturation of AIS and formation of neuronal circuits occur during so called critical periods (CP), which serve to build optimal cortical networks via sensory stimuli and experience during development (Hensch, 2005). This process of activity-dependent

plasticity has been shown in visual cortex (Gutzmann et al., 2014; Schlüter et al., 2017), auditory brainstem neurons (Kuba, 2010; Kuba and Ohmori, 2009) and only recently in somatosensory cortices (Jamann et al., 2021). The ability of neurons to modulate their AIS to respond and adapt to changes of network state, however, is not restricted to early postnatal development but persist throughout adulthood (Jamann et al., 2021). Of note, this mechanism of has only been observed in S1BF, not in the visual cortex (Gutzmann et al., 2014). About 10 years ago, two hallmark papers provided the first evidence for both *in vitro* (Grubb and Burrone, 2010) and *in vivo* (Kuba, 2010) AIS plasticity. Providing depolarizing conditions to the extracellular medium of cultured hippocampal neurons by adding KCl to the solution, resulted in distal relocation of the AIS, which correlated with reduced intrinsic excitability (Grubb and Burrone, 2010). In similar experiments, *Wefelmeyer and colleagues* showed that this relocation process of the AIS along the axon was not accompanied by changes of the position of the axo-axonic synapses from inhibitory ChC (Wefelmeyer et al., 2015). The following mismatch between synapses and the AIS ultimately contributes to decreasing the excitability of the neuron (Wefelmeyer et al., 2015; Figure 7B).

Another form of AIS plasticity was first investigated in *in vivo* deprivational studies of the auditory cortex. Depriving chicks of auditory input caused a lengthening of the AIS, accompanied by elevation of the number of sodium channels, which increased cellular excitability (Kuba, 2019; Figure 7C).

Since then, a multitude of papers provided evidence of the impact of AIS geometry on cellular excitability: Changes in location (Chand et al., 2015; Hamada and Kole, 2015; Hatch et al., 2017), length (Baalman et al., 2013; Evans et al., 2015; Kim et. al., 2019), and ion channel constitution (Kuba et al., 2010; Lezmy et al., 2017) resulted in intrinsic functional changes of neurons in different brain regions.

All these AIS changes seem to serve one purpose: adapting the excitability of individual neurons to changes in presynaptic input. If the input is lost, the neuron increases its excitability via AIS elongation to maintain homeostasis within neuronal circuits. If the neuron experiences increased synaptic input, AIS shorten or relocate distally.

Figure 7: Plasticity of the AIS pt. 2

A: During early postnatal development, AIS of the rodent somatosensory cortex elongate continuously. Upon onset of active whisking and therefore sensory processing in S1BF, AIS shorten abruptly and eventually elongate again to a mature length (based on data in Jamann et al., 2021). **B:** Chronic depolarization leads to relocation or shortening of the AIS. The distance between AIS and the cell soma increases. Those changes cause a decrease in overall excitability of the cell (based on data in Grubb & Burrone, 2010). **C:** Low activity e.g., through sensory deprivation, leads to elongation of the AIS, relocation towards the soma and/or increase of sodium channel expression at the AIS (based on data in Gutzmann et al., 2014; Kuba et al., 2010).

2.5 The rodent basal ganglia

The striatum is the input nucleus of the basal ganglia and integrates information from cortical, thalamic, and limbic regions as well as the midbrain. As there are only limited cognitive and motor resources, it acts as a selection device to separate appropriate from inappropriate behaviors (Redgrave et al., 1999). Its function therefore lies in behavioral learning and motor planning (Burke et al., 2017).

Based on histological markers and anatomical hallmarks, the dorsal striatum can be roughly subdivided into two main areas: the dorsomedial (DMS; Caudate) and the dorsolateral striatum (DLS, Putamen) (Yin et al., 2009).

The DMS receives input from associative areas such as the anterior cingulate area, ventral hippocampus, amygdala, visual, and auditory cortices. It therefore processes and transfers visual, spatial, auditory, and somatic information to the ventromedial PFC and mediates goal-directed behaviors, habits and habit formation (Yin et al., 2009), spatial learning (Devan and White, 1999), and reward expectancy (Hikosaka et al., 2006). The DMS is especially relevant for the development of action-outcome associations during learning and conditioning (Burke et al., 2017; Figure 8).

The DLS receives its main inputs from sensory and motor cortices, insular and orbital areas and is involved in motor planning, action selection, stimulus-response habit learning (Burke 2017), and establishing automated motor sequences (Graybiel, 2008; Yin et al., 2006). Lesions of DLS disrupt habitual behaviors and affect skill learning throughout training (Burton et al., 2015; Figure 8). Retrograde tracing indicated that thalamostriatal and nigrostriatal projections are topographically organized (Lanciego et al., 2004; Pan et al., 2010). Lesions of the trunk region of DLS disrupt the implementation of the stereotyped grooming sequence in rodents (Cromwell and Berridge, 1996). However, there is much overlap between those areas regarding function (Isomura et al., 2013).

Figure 8: Input and output of the dorsal striatum

DLS and DMS receive input (green) from various cortical regions. The DLS receives its main input from sensory, motor, insular, and orbital cortices. The DMS receives its input from associative areas, including ventral hippocampus and visual cortex. Main output (grey) of the DLS play a major role in motor planning and action selection, whereas the DMS is more involved in goal-directed behavior and reward expectancy.

Approximately 95% of striatal neurons are GABAergic medium spiny neurons (MSN) e.g. spiny projection neurons (SPN; Gravel and DiFiglia 1985). They can be subdivided into three groups, depending on their dopamine receptor expression patterns and neurochemical content. Double staining of transgenic mice showed that the overall density of dopamine receptor 1 (D1) expressing SPN is just slightly higher than the density of dopamine receptor 2 (D2) expressing SPN (approx. 51% compared to 46% of all SPN, respectively). The latter are evenly distributed throughout the striatum (Gagnon et al., 2017; Ren et al., 2017). D1 expressing SPN express the neuropeptides substance P (SP) and dynorphin (DYN) and project mainly to substantia nigra pars reticulata (SNr) and the entopeduncular nucleus (EP), which is the rodent equivalent to the internal pallidum (GPi). Those are the GABAergic projections of the direct pathway (Figure 9). D2 expressing SPN contain enkephalin (ENK) and send GABAergic axonal projections mainly to the external pallidum (GPe), which then forwards projections onto the GPi/SNr, this resulting in the indirect pathway. A small population of SPN (2-5%) in dorsal striatum expresses both D1 and D2

receptors. They were found to have a smaller cell body, shorter dendritic arborization and 37% lower spine density (Gagnon et al., 2017). The function of those SPN is yet not fully understood. Neurons in substantia nigra, pars compacta (SNc) release dopamine, which activates D1 and inactivates D2 receptors (Tritsch and Sabatini, 2012).

Figure 9: Basal ganglia circuits

A: Anatomical location of important components of the basal ganglia and its functional circuits. Sagittal section of the adult mouse brain modified after (Paxinos). **B:** Both pathways (direct and indirect) exhibit their influence on the thalamus via the globus pallidus internus (GPi) and substantia nigra pars reticulata (SNr), an equivalent to the rodent entopeduncular nucleus (EP). GPi/SNr sends inhibitory GABAergic afferents to the thalamus to inhibit movement and behavior. The direct pathway inhibits the GPi/SNr via GABAergic inputs from the striatum (CPu), which ultimately promotes thalamic function. The indirect pathway has additional synapses, passing through globus pallidus externus (GPe) and STN. This last glutamatergic synapse promotes the inhibitory function of GPi/SNr. The hyperdirect pathway sends glutamatergic projections through the subthalamic nucleus (STN) to GPi/SNr.

In the case of the direct pathway, neurons of the GPi/SNr are inhibited by GABAergic input from the striatum, which ultimately promotes thalamic function. The indirect pathway has an additional GABAergic synapses while passing from the striatum through GPe and STN to GPi/SNr. This additional last glutamatergic synapse leads to inhibition of thalamic function and thus presents an opponent to the direct pathway (Figure 9). The third, hyperdirect pathway, acts as a suppressor of ongoing automated body movements, allowing planned movements to be initiated properly (Isoda and Hikosaka, 2008). Excitatory projections from the thalamus back to the cortex form a feedback-loop. Rather than controlling voluntary movement in an antagonistic manner, the indirect and

the direct pathways show much overlap in function and tend to work cooperatively to integrate information and facilitate behaviors (Barbera et al., 2016). Fiberoptics and time-correlated single-photon counting revealed concurrent activation of both pathways especially during the initiation of actions (Cui et al., 2013). Also, both pathways are necessary for the smooth execution/coordination of actions (Tecuapetla et al., 2016). While D1 neurons are responsible for executing the movement, D2 neurons suppress antagonistic muscular movement, and the impairment of any of the two pathways disrupts ongoing function in both pathways (Isomura et al., 2013).

Only 5% of all striatal neurons are interneurons, either cholinergic (CIN) or GABAergic (Tepper et al., 2018). Anterograde tracing revealed that CIN receive more thalamic than cortical input (Lapper and Bolam, 1992). During conditioned motor tasks, CIN pause their tonic firing, which was shown to be important for sensorimotor learning and coordination (Zhou et al., 2002).

There are three main types of GABAergic interneurons: fast-spiking (FSI), low-threshold spiking (LTSI), and calretinin-expressing (CRI) interneurons. They receive mostly cortical input (Lapper et al., 1992). FSI express parvalbumin (PV) and fire AP at high frequencies, thereby inhibiting SPN. PV knockout mice show abnormalities in social interaction, communication, and repetitive behavior, all of which are key symptoms of ASD. Heterozygous mice also show symptoms, showing that reductions of PV levels already are sufficient to reproduce core symptoms and altered E/I synaptic transmission (Wohr et al., 2015).

Increased levels of synaptic DA transmission in DLS promotes autistic-like behavior such as social deficits and repetitive grooming in rodents (Lee et al., 2018). The AP frequency of SNc dopaminergic neurons sets the baseline DA level in the brain. *In vivo* recordings followed by computational modelling indicated that the spontaneous tonic firing rate of nigral neurons is dependent on AIS length and distance from the soma (Meza et al., 2018). Modulating the size and proximity of the AIS, which is known to modulate AP frequency and excitability, could therefore contribute to altered DA levels that influence the motor, cognitive, and behavioral output of the striatum (Meza et al., 2018).

Similar patterns of connectivity between rodents and humans implicate that they are evolutionarily conserved in mammals, justifying rodent models to study human ASD correlates (Keifer et al., 2015). Taken together, there is a lot of evidence promoting striatal processing abnormalities as a neural correlate of ASD core symptoms, with disruptions of dorsal striatal function leading to the display of autistic features (Chang et al., 2015; Lee et al., 2018).

2.6 The rodent somatosensory cortex

The whiskers are of great importance for rodents, as they are nocturnal animals and depend on their tactile sensors to compensate poor visual acuity. The rodent primary somatosensory cortex receives input from the thalamocortical axons of the ventroposterior medial nucleus (VPM), which is organized in a somatotopic manner (Pan et al., 2010).

Distinct cytoarchitectonic units in layer IV, called “barrels”, are topographic cortical representations of rodent facial whiskers of the contralateral side of the snout (Erzurumlu and Gaspar, 2012; Woolsey and Van der Loos, 1970). This resulted in naming this cortical structure based on its somatotopic organization principal the somatosensory barrel field (S1BF).

For sensorimotor integration and sensory perception, S1BF sends long-range connections to other regions, such as the secondary somatosensory cortex, motor cortex, thalamus, and the striatum (Aronoff et al., 2010). Projections to the DLS derive mainly from infragranular layers and exhibit their influence on motor control and action selection (Aronoff et al., 2010). The long subcortical loop is completed by axons that project from the striatum to the thalamus and back to the neocortex.

S1BF, like other parts of the neocortex, consists of six layers, that have been first described by Santiago Ramón y Cajal (Cajal, 1899; Figure 10). The most superficial is layer I, mostly consisting of dendrites and axons that extend upwards from lower layers. Layers II and III contain pyramidal neurons that project to the thalamus and form the origin and termination of intracortical

connections. Layer IV is the main input layer of the cortex, receiving connections from the thalamus and is very prominent in primary sensory cortices such as S1BF. The distinct organization of layer IV in barrel and septal regions, that is exclusive for the somatosensory cortex, is maintained in layer V (Wright and Fox, 2010) and even further downstream in the brainstem and the thalamus, where the patterns are termed “barrelettes” and “barreloids”, respectively (Van Der Loos, 1976). Layer V contains large pyramidal cells, which constitute the origin of projections to the basal ganglia, the brain stem, the spinal cord and other extracortical regions. In S1BF, the information that is processed and the projections are depending on the location in barrel and septal regions: neurons of septal columns encode the frequency and kinetic features of active whisker movements and primarily send information to the motor cortex as well as they form bilateral connections with the contralateral barrel cortex (Alloway, 2008). Barrel-related neurons encode the spatio-temporal information of whisker movement. Together, they send projections to the secondary somatosensory cortex (Chakrabarti and Alloway, 2006). However, layer V is subdivided into two layers Va and Vb. Dense thalamical input from the ventral posteromedial nucleus (VPM) sends information to layer Va neurons, whereas the posterior medial thalamic nucleus (POm) sends its information to layer Vb, both carrying different lemniscal and paralemniscal information to the cortex (Bureau et al., 2006). Layer Va neurons in turn send their projections to the striatum, layer Vb to pontine nuclei in the brain stem (Mercier et al., 1990).

The deepest layer, layer VI, forms the transition to the white matter and consists of mixed granular and pyramidal neurons. Its projections are primarily to the thalamus.

Figure 10: The cytoarchitecture of the barrel cortex

A: Drawing of the layers of the human sensory cortex by Santiago Ramón y Cajal, published in “Comparative study of the sensory areas of the human cortex” (Cajal 1899). Six layers form distinct input and output zones. Further details are described in Chapter 2.5. **B:** Schematic illustration of the different intracortical projections in S1BF.

At birth, the somatosensory system is still immature. Cortical circuits shape and fine-tune during distinct CPs, in which connections are adaptive to changes of sensory input (Jamann et al., 2018). Deprivation of sensory information input during CPs due to vibrissotomy contributes to changes in the cortical representation of the affected and adjacent whiskers and reshaping of somatotopy (Melzer and Smith, 1995). This is very important for perceptual learning, but also as an adaptation mechanism due to injuries or disease. This effect is not limited to S1BF but extends to other sensory areas in the cortex (Gutzmann et al., 2014; Kuba and Ohmori, 2009; Schlüter et al., 2017).

It has been previously shown that the AIS undergoes significant structural remodeling during the development of sensory systems. AIS length steadily

increases until the sudden onset of sensory input. This has been shown in the visual cortex, where AIS shorten after eye opening at P14 (Gutzmann et al., 2014) and in the somatosensory cortex after the onset of active whisking at P12 (Jamann et al., 2021; Figure 6).

Impaired somatosensory processing such as hyperreactive and/or aversive response to tactile stimuli is associated with ASD and Fragile-X Syndrome (Cascio, 2010). Deficits in tactile perception and hypo-responsiveness contribute to the presentation of ASD-associated symptoms and are correlated with increased impairment in social communication and repetitive behavior (Foss-Feig et al., 2012). Deprivation of tactile information due to whisker-trimming also impacts the amygdala and leads to increased responsiveness to fear- and anxiety-related stimuli, common comorbidities of autism (Soumiya et al., 2016).

2.7 Objectives

As outlined above, the AIS plays an important role in the dynamic regulation of cellular excitability and neuronal circuit function (Engelhardt et al., 2019; Jamann et al., 2018; Kole and Brette, 2018). An imbalance of excitation and inhibition in the fronto-striatal circuitry has been implicated in the development of typical ASD phenotypes. In this context, the hypothesis of the AIS serving as a homeostatic regulator of intrinsic excitability might provide a novel experimental basis to further our understanding of underlying mechanisms in the development of ASD.

The following questions were therefore addressed in this thesis:

- Does VPA-exposure have an impact on the development of the AIS in supragranular and infragranular pyramidal neurons in mouse S1BF?
- Is the axo-axonic innervation pattern at the AIS altered after VPA-exposure?
- Does VPA-exposure affect intrinsic neuronal excitability in S1BF?
- Does the AIS also exhibit structural changes in a genetic model of ASD?

- What are differences and commonalities regarding AIS development between pharmacologically induced and genetical mouse models of ASD?

Taken together, the data show that the maturation of the AIS is impacted by VPA-exposure in a layer-specific manner in S1BF, while inhibitory synaptic innervation patterns at the AIS remain unchanged. AIS remodeling occurred as a result of VPA exposure and FOXP1 heterogeneity. Morphological and electrophysiological data suggest that layer V might be involved in homeostatic changes due to VPA exposure and that this might affect downstream pathways. Lastly, morphological changes of the AIS of the DLS in both rodent models might present a commonality in the etiology of ASD typical phenotypes.

3 MATERIAL AND METHODS

Detailed information about equipment and software used can be found in the appendix.

3.1 Experimental Animals

3.1.1 FOXP1 heterozygous mice

All procedures were approved by the Institutional Animal Care and Use Committee (IACUC) of University of Texas Southwestern Medical Center, Dallas, TX, USA.

To obtain congenic animals, homozygous-floxed *Foxp1* (*Foxp1*^{flox/flox}) mice were backcrossed with wildtype C57BL/6J, *Emx1-Cre* (Jackson Laboratory, 005628) mice for at least generations as previously published (Araujo et al., 2015; Usui et al., 2017). Both female and male mice were used in this study. Mouse brains were obtained in fixed, frozen condition from the lab of Prof. Genevieve Konopka, Department of Neuroscience, UT Southwestern Medical Center, Dallas, TX, USA.

3.1.2 VPA exposure

All experiments were conducted according to the guidelines on the care of laboratory animals of Heidelberg University, Medical Faculty Mannheim and the present European animal welfare being laws. Protocols were reviewed and approved by Heidelberg University, Medical Faculty Mannheim as well as the administrative council of the State of Baden-Württemberg, Karlsruhe (Reference Number G67/16). Pregnant wildtype mice of the C57/BL/6 stain (Janvier Labs, France) were purchased at gestation day 6, then injected with VPA at gestation day 13. Mothers and their mixed-gender offspring were kept in the animal house under regular supervision and were maintained with water and food *ad libitum* and on a regular 12 h/12 h light/dark cycle, at a temperature of 22± 2 °C and relative humidity of 45-65%. Young mice (P3, P15) were kept with their mothers; older animals (for experiments at P45) were separated from their mothers as usual at P28.

Prenatal exposition with valproic acid (VPA) was conducted as previously published (Mehta et al., 2011). NaVPA salt was diluted in 0.9% NaCl to a concentration of 300 mg/ml, pH 7.3 (Table 1). According to body weight, mothers were injected with 600 mg/ kg (2 ml/ kg bw) NaVPA *i.p.* at gestation day 13. Mothers of the control group were injected with an equivalent amount of 0.9% NaCl. All tissue preparation and staining protocols were identical in both groups.

Table 1: Chemicals and Solutions for VPA Exposure

Chemical/ Solution	Composition	Source
IsofluranCP		CP Pharma, Burgdorf, Germany

3.2 Immunofluorescence

3.2.1 Tissue preparation for developmental series

Mothers at gestation day 18 of both experimental groups were deeply anaesthetized by intraperitoneal injection of Ketamine (Ketavet, 65 mg/kg bw; Table 5) and Xylazine (Rompun®, 13 mg/kg bw, Table 5) diluted in 0.9% NaCl. Embryos were manually extracted from their mothers and instantly decapitated. The brains were isolated in ice-cold phosphate buffered saline (PBS, Table 6) under optical guidance and immersion fixed by incubation in 2% paraformaldehyde (PFA, Table 6) for 4h at room temperature (RT).

Animals at P3 were decapitated and brains were dissected in ice-cold 0.1M PBS, then fixed by immersion in 4% PFA (in 0.1M PBS, pH 7.4, 5 min, 4°C, Table 6). After fixation, all tissue was cryoprotected by sequential incubation in 10% sucrose solution overnight and in 30% sucrose solution for another 48 h at 4 °C (Table 6).

Animals at P15 and older were deeply anaesthetized with Ketamine (Ketavet, 65 mg/ kg bw; Table 5) and Xylazine (Rompun®, 13 mg/kg bw; Table 5) diluted in 0.9% NaCl (Table 6). After insertion of the cannula through the left heart chamber to the aorta, animals were exsanguinated with 0.9% NaCl under pressure, followed by 15 min perfusion with ice-cold 2% PFA solution. The brains were then extracted from the skull without any further fixation steps, then cryoprotected by sequential incubation in 10% sucrose solution overnight and in 30% sucrose solution for another 48 h at 4 °C.

The Tissue was embedded in TissueTek® (Sakura Finetek; Table 5) and immediately frozen in liquid Isopentane (2-Methylbutan, Table 5) cooled by liquid nitrogen. The blocks were stored at -20 °C continuously until further processing.

After electrophysiological recording, acute slices of animals at P15 were fixed free-floating for 30 min in 4% PFA at RT, then stored in PBS at 4°C until further processing (Table 5).

3.2.2 Immunostaining procedures

For immunofluorescence, 20 µm sections were cut using a cryostat and were either collected directly on slices or stored in cryoprotective solution (Table 6) as free-floating sections. As previous studies in our lab showed no difference in AIS length using these different methods (Gutzmann et al., 2014), both were used in this study.

Slices were washed 3 x 5 min in PBS, then incubated in fish skin gelatin blocking buffer (1% BSA, 0.2% fish skin gelatine, 0.1% Triton; Table 6) at RT for 60 min in order to block all non-specific binding sites. Incubation with primary antibodies (Table 3) diluted in dilution buffer (1% fish skin gelatine, 0.1% Triton, diluted in 1x PBS; Table 6) was carried out over night at RT. On the next day, sections were washed 3 x 5 min in PBS to remove redundant primary antibodies, then incubated with secondary antibodies for 2 h (Table 4) at RT and in the dark. Finally, sliced were immersed in mounting medium (Roti-Mount Fluor Care, Carl-Roth; Table 5) and protected by a cover slip for confocal microscopy.

For acute slices, in order to increase the penetration of the antibodies, sections were incubated in PBS containing 0.2% Triton-X100 for 2h. Blocking time in blocking buffer (1% BSA, 0.2% fish skin gelatine, 0.2% Triton; Table 6) was to 2h. The incubation time of the primary antibodies was also increased to 24 h at 4°C, followed by thorough washing steps in PBS (2 h, changed every 30 min). Secondary antibodies were applied over night at 4 °C. After washing for 2 h, sections were transferred to slides and allowed to dry over night at 4 °C. Lastly, sections were covered in mounting medium (Roti-Mount Fluor Care, Carl-Roth; Table 5) and stored at 4°C until processing.

For immunohistochemistry, tissue was prepared as outlined in section 3.2.1. Free floating sections were washed 3 x 5 min in PBS, then incubated in blocking buffer (1% BSA, 0.2% fish skin gelatine, 0.1% Triton; Table 6) for 20 min. Sections were then incubated with the primary antibodies (Table 3) overnight at RT, then washed twice for 5 min in PBS before applying 3% H₂O₂ for 5 min to block the endogenous peroxidase. After further washing (3 x 5 min in PBS), sections were incubated with the secondary antibodies (Table 4) for 30 min at

RT, washed again (3 x 5 min in PBS), followed by incubation with Streptavidin-peroxidase (Streptavidin-POD; Table 6) for 30 min at RT. 3,3'-Diaminobenzidine (DAB)-staining of the peroxidase was carried out under visual control. Slices were incubated with DAB-buffer solution (1:10; Fa-Roche; Table 6) until the color and intensity of the staining was appropriate. This step was followed by dehydration and clearing in ethanol (3 x >99% ethanol; Table 6), Tissue Clear (2x, Sakura Finetek; Table 6), and n-Butyl acetate (Carl-Roth; Table 6) prior to permanent mounting in Histofluid (neoLab; Table 6).

Table 3: Primary antibodies used for immunofluorescence

Antibody (host)	Dilution	Target	Epitope/ Sequence	Clone/ type	Source
Actin (rabbit)	1:5000 (WB) 1:2500	C-terminus of human actin		polyclonal	Santa Cruz Biotechnology, Santa Cruz, USA
Ankyrin-G (rabbit)	1:500 (IF) 1:100 (WB)	AIS scaffold	Amino acids 4163-4377 at the C-terminus of human ankG, clone H-215	polyclonal	Santa Cruz Biotechnology, Santa Cruz, USA
Ankyrin-G (mouse)	1:500 (IF) 1:100 (WB)	AIS scaffold	Fusion protein, ~1000 amino acids of ankG, clone N106/36	monoclonal	UC Davis/NIH NeuroMab Facility, CA, USA
β IV-spectrin (rabbit)	1:1000 (IF) 1:2000 (WB)	AIS scaffold	Recombinant protein corresponding to Human β IV spectrin, amino acids 2237-2256	polyclonal	Selfmade, Biotrend Chemikalien GmbH, Cologne, Germany
KCNQ2 (mouse)	1:500 (WB)	KV7.2/ KCNQ2 Potassium channel	Fusion protein amino acids 1-59 (cytoplasmatic N-terminus) of human KCNQ2 clone 26A/23	monoclonal	UC Davis/NIH NeuroMab Facility, CA, USA
PanNav (rabbit)	1:1000 (WB)	Sodium channels	Synthetic peptide CTEEQKYYNAMKLGSKK from the intracellular III-IV loop of Na ⁺ channels, clone K58/35	monoclonal	Sigma, St. Louis, USA
Nav (rabbit)	1.61:500 (IF)	sodium channel, AIS specific	Amino acid residues 1042-1061 of rat Nav1.6 intracellular loop between domain II and III	polyclonal	Alomone Labs, Jerusalem, Israel
NeuN (mouse)	1:1000 (IF)	Cell soma	IgG, purified cell nuclei (mouse brain)	monoclonal	Millipore, Temecula, USA

Antibody (host)	Dilution	Target	Epitope/ Sequence	Clone/ type	Source
NeuN (guinea pig)	1:1000 (IF)	Cell soma	N-terminus of Neu-N, GST-tagged recombinant protein corresponding to ms NeuN	polyclonal	Millipore, Temecula, USA
TH (sheep)	1:500	Dopaminergic neurons	Full-length native protein corresponding to rat TH	polyclonal	Abcam, Cambridge, England
FOXP1 (rabbit)	1:1000	FOXP1 protein	Synthetic peptides corresponding to residues of Asp666 of human Foxp1	polyclonal	Cell Signaling, Frankfurt, Germany
Calbindin (mouse)	1:1000	Calbindin protein	IgG, D-28k	monoclonal	Swant, Bellinzona, Switzerland
Enkephalin (rabbit)	1:2000 (IF)	D1 SPN	IgG, pre-pro Enkephalin (NBP2)	polyclonal	Novusbio, Centennial, USA
Parvalbumin (guinea pig)	1:500 (IF)	GABAergic interneurons	Recombinant full-length rat parvalbumin	Polyclonal	Synaptic Systems, Göttingen, Germany
GABA (guinea pig)	1:250 (IF)	Inhibitory neurons, postsynapse	Synthetic peptide (Amino acids 29-37), precursor protein	Polyclonal	Synaptic Systems, Göttingen, Germany
VGAT (chicken)	1:250 (IF)	Vesicular GABA transporter, inhibitory presynapse	Synthetic peptide (Amino acids 75-87), couples to key-hole limpet hemocytain	Polyclonal	Synaptic Systems, Göttingen, Germany

WB: Western blot, IF: Immunofluorescence, TH: tyrosine hydroxylase

Table 4: Secondary antibodies

3.3 Western blot

3.3.1 Tissue preparation

Tissue samples of striatum and cortex were obtained from the brains of adult FOXP1^{+/-} and FOXP1^{+/+} mice as well as VPA-injected and control mice at 4 different developmental stages. At P3, the striatum and cortex were not separated due to anatomical limitations. Whole brains of animals at P3 were immediately extracted from the skull and frozen. Brains from older animals were carefully cut into 1 mm slices using a tissue matrix slicer (Zivic Instruments, Table 22). The slices were then placed into PBS, where the striatum and S1BF were dissected under visual control using a binocular microscope. Animals at P15 and older were transcardially perfused with ice-cold 0.9% NaCl as described previously (Section 3.2.1) before the brains were extracted.

The samples were diluted in ice-cold homogenization buffer (20 mM Tris, 0.5 M NaCl, 8 mM CHAPS, 6.4 mM EDTA, pH 7.5; Table 8) together with protease inhibitor (Complete mini, ThermoFisher Scientific; Table 8) and phosphatase inhibitor (Phosstop, ThermoFisher Scientific; Table 8). Samples were then homogenized by pulsed ultrasonication and completely lysed for 60 min under constant agitation on an orbital shaker (4°C, 350 rpm). After centrifugation for 45 min (4°C, 13.000 rpm) to remove insoluble components of the sample, the supernatant was aspirated and stored in an ice-cold fresh tube, while the pellet was discharged. The tubes were then frozen in liquid nitrogen and stored until further processing at -80 °C.

Protein concentration was evaluated via Bradford protein quantification assay. The calibration solution to produce a calibration scale was produced by attenuating BSA in aqua dest. in the following concentrations: 100 µg/ml, 80 µg/ml, 60 µg/ml, 40 µg/ml, 20 µg/ml, 10 µg/ml and 0 µg/ml as a control. 5 ml Roti nanoquant (Carl Roth; Table 7) was diluted in 20 ml aqua dest. Measurements were carried out in transparent 96-well plates. The lysates were thawed and diluted in aqua dest. to a concentration of 1:100. For subsequent gradient gels, tubes containing 20 µg of tissue sample and Laemmli buffer (2% SDS, 60 mM Tris-Cl, 10% glycerol, 5% β-mercaptoethanol, 0.01% bromphenol

blue; Table 8) were heated up to 70°C for 10 min. Tubes were then stored at -20 °C and blotted on the following days.

Gradient gels (3-8% Tris-Acetate protein gels, ThermoFisher Scientific; Table 7) were used to allow the visualization of large proteins (e.g. 480kDa ankG) and small proteins (e.g. 40kDa actin) simultaneously on one membrane. Gels were loaded and run in Tris-Tricine buffer (50 mM Tris, 50 mM Tricine, 0.1% SDS; Table 8) for 55 min. at 150V/300mA.

The blotting membrane was activated in 100% methanol for 1 min. After separation by gel electrophoresis, the samples were transferred onto the blotting membrane. According to the estimated molecular weight, the membrane was cut into three separate stripes according to previously published protocols (Engelhardt et al., 2017, Jamann et al., 2021). All Western blot buffers were diluted in 1000 ml aqua dest. and cooled at -20 °C for at least 30 min. The blotting chamber was placed in a plastic bowl filled with ice and placed in a 4 °C temperature-controlled room. Blotting was performed at 550 mA in Tris-Glycine buffer at constant 4°C:

The following blotting protocol was applied:

- 1) Tris-Glycine buffer 1 (25 mM Tris-base, 192 mM Glycine, 20% methanol; Table 8). After this first step, the membrane strip with the protein of the smallest molecular weight was removed. The membrane strip was stored in PBS.
- 2) The buffer was exchanged to Tris-Glycine buffer 2 (25 mM Tris-base, 192 mM Glycine, 15% methanol, 0.05% SDS; Table 8) and run for 30 min. After the second step, the middle membrane strip was removed and stored in PBS.
- 3) Blotting buffer was then again exchanged for Tris-Glycine buffer 3 (25 mM Tris-base, 192 mM Glycine, 0.1% SDS; Table 8) and the last strip was blotted for 90 min.

Membranes were blocked in PBST at RT for 2 h on a shaker, then the primary antibody was applied at 4 °C overnight (Table 3). On the next day, membranes were washed 3 x 5 min in PBS, then incubated with the secondary antibody

(Table 4) diluted in PBST for 90 min at RT, again under agitation. Before development, the membranes were washed again (3 x in PBS).

Ultimately, protein signals were revealed using an ECL Kit (Western Bright ECL HRP substrate, Advansta; Table 8) and imaged (Fusion solo, Vilber Lourmat; Supplementary Table 22).

3.4 Electrophysiology

3.4.1 Preparation and solutions

Artificial Cerebral Spinal Fluid (ACSF: 125 mM NaCl, 2.5 mM KCl, 1.25 mM NaH₂PO₄, 25 mM NaHCO₃, 1 mM MgCl₂, 2 mM CaCl₂, 25 mM Glucose; Table 16) was freshly prepared on the day of the recordings and continuously supplemented with carbogen gas (95% O₂, 5% CO₂). After preparation of the sucrose-based cutting solution (206 mM sucrose, 2.5 mM KCl, 1.25 mM NaH₂PO₄, 25 mM NaHCO₃, 25 mM Glucose, 3 mM MgCl₂, 1 mM CaCl₂, pH 7.4; Table 16) it was supplemented with carbogen gas (95% O₂, 5% CO₂) on ice for 60 min, this solution was then frozen for 30 min at -80 °C. The frozen solution was briefly blended to achieve a slushy consistency.

To prepare acute slices, mice were deeply anesthetized with Isoflurane (Table 5) then swiftly decapitated and the brains placed into the ice-cold sucrose-based cutting solution. Full brains were trimmed to 300 µm thick slices in a rostral to caudal coronal manner using a vibratome (VT 1200 S, Leica Biosystems; Table 30). Slices were transferred to a slice holder and incubated in carbonated ACSF for at least 30 min at RT before recordings began.

3.4.2 Recordings

Measurements were carried out at RT. Patch pipettes were pulled out of borosilicate glass capillaries (outer diameter 1.5 mm, inner diameter 0.8 mm) using a Flaming/Brown Micropipette puller to the tip resistances of 3.5-5 mΩ (for Equipment and Software: Supplementary Table 23), then filled with the intracellular solution (140 mM K-gluconate, 3 mM KCl, 4 mM NaCl, 10 mM HEPES, 0.2 mM EGTA, 2 mM MgATP, 0.1 mM NaGTP; Table 9). For post-hoc identification of the recorded neuron, 3 mg/ml biocytin was added to the intracellular solution. Slices were transferred into the recording chamber and held in place using a harp. An upright Nikon Eclipse FN1 microscope with an IR-DIC contrast filter (Table 23) was used to visualize pyramidal neurons of layer II/III and V. The identification of neurons and correct allocation to their specific layer was confirmed via post-hoc immunofluorescence. Measurements

were conducted using a HEKA EPC10 USB amplifier controlled by Patchmaster Software (HEKA Electronics, Germany, Table 23).

The recordings were lowpass filtered at 3kHz (Filter 2) and 10kHz (Filter 1) and sampled at 50kHz. Liquid junction potential was corrected for measurements (estimated for -12mV). Resting membrane potential (RMP) was taken directly after rupture of the cell membrane in current-clamp mode prior to any stimulus injections. In current-clamp mode, intrinsic firing properties were measured with a protocol of incremental series of current steps, starting at a holding current of $I=0$. Increasing steps of 10 pA and a duration of 20 ms were applied to elicit changes in membrane voltage and ultimately to trigger APs. AP current threshold was defined at the first pulse of 20 ms that produced reliable APs. The threshold rate of 50mV/ms was determined as the starting point of the rising phase of the AP and therefore set as voltage threshold. AP amplitude was defined as the difference between voltage threshold to peak voltage, AP half width was defined as width at the middle voltage of AP amplitude. To analyze firing patterns and produce series of AP, 500 ms pulses incrementing in 50pA steps were applied.

Only cells with a series resistance (R_s) <30 m Ω and less than 15% change during recording were included in the analysis. Spontaneous excitatory postsynaptic currents (EPSPs) were recorded for 2 min at -70 mV.

After recordings were completed, sliced were fixed in 4% PFA for 20 min at RT, then stored in PBS until further processing.

3.4.3 Chemicals and Solutions

Table 9: Solutions used for electrophysiology

Solution	Composition	Source
Sucrose-based cutting solution	In ddH ₂ O

3.5 Analysis

3.5.1 Confocal Laser Scanning Microscopy

Confocal imaging was carried out using a C2 Nikon laser scanning confocal microscope (Nikon Instruments, laser lines: 642, 543, and 488 nm, Table 21) with an 60x objective (oil immersion, numerical aperture of 1.4) and a SP5 confocal microscope (Leica, Mannheim; laser lines: Ar 488 nm/ 20 mW and 514 nm / 20 mW, DPSS 561 nm/ 20 mW, HeNe 633 nm /10 mW, Table 21) with a 63x objective (oil immersion, numerical aperture of 1.4). Detector and amplifier offsets were individually adapted due to pixel intensities and staining quality at following conditions: scan speed ¼, scan size 1024x1024 pixels. Maximum intensity projection overlay images were created from z-stacks to increase the probability of capturing immunoreactive structures such as full length AIS in focus. Stacks were scanned using a step size of 0.5 µm per optical slice.

3.5.2 AIS length analysis in AISuite

AISuite is a self-written morphometrical software (Roos & Engelhardt, unpublished; open-source link: github.com/jhnnrs/aisuite2; Table 25), which enables the user to manually select AIS according to the following parameters:

- proximal and distal end of the AIS could be clearly identified
- AIS emergence from one specific soma could be clearly distinguished
- immunosignal showed no disruptions or gaps along the length of the AIS

A line was drawn through the length of the AIS extending into the soma as well as the distal end (Figure 11). By making sure that the line exceeded the actual AIS length, the measurements were then provided by the software only and not affected by personal selection bias. The plotted line was straightened, and fluorescence intensity was plotted against the length of the selected line.

The maximum intensity of each individual selected AIS was defined as 100%, the threshold was then set at 20%. To cut off background noise due to staining artefacts, threshold could manually be adapted as needed for adequate analysis. The first pixel to reach threshold level determined the beginning of the

AIS, the last pixel determined the end. AIS length in pixel was then converted to μm according to the settings and calibration of the confocal microscope. (at $60\times = 0.21 \mu\text{m}/\text{pixel}$). The software then provides an automated read-out of various AIS parameters such as length and distance to the soma.

Figure 11: AIS length analysis with AISuite

A: Original maximum intensity projection image in AISuite, arrow: AIS, example used for further analysis in (B-E). Image size: 1024 x 1024 px, also applies for B. **B:** Selection and marking of the AIS. Box indicates 200 x 200 px. **C:** Straightened AIS. **D:** Fluorescent intensity profile from AIS selected in C. The intensity was plotted against the length of the selected line in (C). Maximum intensity was detected for each individual AIS and defined as 100%, threshold was set at 20% of the maximum intensity. Beginning and end of the AIS were detected whenever threshold was reached first and last (*). Length in pixels was converted to μm based on the calibration of the confocal microscope settings at 60 x ($0.21 \mu\text{m}/\text{pixel}$).

3.5.3 Multi-channel immunostaining of GABAergic synapses

Images for multi-channel immunofluorescence were acquired using a Leica SP5 MP combined multi-photon and confocal laser scanning microscope with a 63x objective (Section 3.5.1). Lasers and excitation wavelength were adjusted according to the optimum of each slice. Stacks of images were produced, increasing the number of in-focus structures, then fused into maximum intensity projections and saved.

Acquired z-stacks were edited to optimize analysis and identification of synaptic structures. Z-stacks were subjected to deconvolution using AutoQuant X3® (Media Cybernetics, USA; Table 25) software. After 3D deconvolution, the images were transferred to and Imaris® (Bitplane, Switzerland; Table 25) software for further 3D reconstruction of the AIS and its synaptic structures. All reconstruction procedure was followed as instructed by the software, including adjustments regarding background noise subtraction.

GABAergic synapses were manually selected after image deconvolution and processing using the following criteria:

- AIS must be clearly identified as such (see criteria from 3.5.2)
- GABA_AR α_2 and VGAT puncta must be easily and clearly distinguishable from background noise.
- GABA_AR α_2 are situated in direct contact with the membrane of the AIS with approximately one half of the object being located at the inside of the AIS and the other on the surface. GABA_AR α_2 cannot be completely located on the inside of the AIS.
- VGAT and GABA_AR α_2 clusters must display close approximation (the synaptic cleft is approx. 40 nm *in vivo*, so for our analysis, the clusters had to interlace and not be separated by a visible gap considering the limitations of resolution in confocal z-stack images).

If all criteria were met, reconstructed GABAergic synapses were counted along the AIS to compare total synapse numbers between VPA-exposed and control mice.

3.5.4 Analysis of electrophysiological recordings

Data was analyzed using the following programs: Fitmaster Software (HEKA Electronics, Germany; Table 25), OriginPro 8 (Origin lab cooperation, USA; Table 25) and AxoGraph (AxoGraph Scientific, John Clements, USA; Table 25).

3.5.5 Analysis of gradient gels

Data was analyzed using Image J software (Table 25). Samples were normalized against the internal loading control (actin).

3.6 Data presentation and statistics

For each experimental group, the mean value and standard deviation (SD) of the AIS length was calculated in at least 6 animals, at least 100 AIS per animal ($n = 6$). Data were analyzed using SigmaPlot 12.5 Software (Systat Software GmbH; Table 25) and GraphPad Prism 8 software (GraphPad Software, Inc.; Table 25). According to literature, only AIS $>10 \mu\text{m}$ were considered for statistical analysis. For the comparison of two parametric and non-parametric groups, t -test and Kruskal-Wallis test were carried out, respectively. For normally distributed comparisons of more than two groups, an ordinary One-way ANOVA was carried out, followed by post-hoc correction (Tukey's multiple comparisons). If the samples were not normally distributed, a One-way ANOVA on ranks was performed. Details are given in the legends of the figures. Results are given as P values with significant differences indicated as $* = P < 0.05$). The specific tests, P values and number of samples and animals are stated in each figure legend.

4 RESULTS

In this thesis, we examined the morphology of the AIS in two well-established mouse models of ASD. Different properties of the AIS such as length, ion channel distribution, and the number of inhibitory synapses were investigated and compared to wildtype controls. With this characterization of AIS plasticity, we aim to find structural and functional correlates that possibly contribute to the autistic phenotypes on a single neuron level.

4.1 Implementation of the AIS staining protocol

The AIS can be visualized through immunofluorescent staining with antibodies against its main scaffolding proteins ankG and β IV-spectrin. Antibodies and staining protocols have been previously tested and established in our laboratory (Gutzmann et al., 2014; Höfflin et al., 2017; Jamann et al., 2021; Schlüter et al., 2017). In this thesis, primary and secondary antibodies (Table 3; Table 4) were chosen depending on suitable combinations of host species to achieve optimal staining results. Using the well-established staining protocols guaranteed reproducible and consistent results. However, while previous protocols were tested for specific cortical areas of the mouse brain such as the visual cortex (Gutzmann et al., 2014), motor cortex (Benedetti et al., 2020) or hippocampus (Thome et al., 2014), appropriate protocols for striatal areas had to be established.

Testing antibodies in different concentrations, combinations and from different host species lead to the following conclusions:

- Ms anti-ankG and rb anti- β IV-spectrin antibodies consistently stained the AIS in striatal areas throughout all ages tested (P3, P15, P45, >P45). Both are suitable to stain the AIS for AIS length measurements.
- Co-staining of ms anti-ankG with rb anti-enkephalin produced evenly stained AIS in both main cell types of the striatum: enkephalinergic D1-MSN and DYN-containing D2-MSN (Figure 12).

- Co-staining of the Nav_v1.6 sodium channel isoform with β IV-spectrin revealed the same co-localization at the AIS as found previously in the cortex and is supported by the literature (Zhou et al., 1998). These stainings served to measure fluorescent intensity of ankG and Nav_v1.6 along the mean length of the AIS for correlation analysis (Figure 13).

Figure 12: Implementation of AIS staining protocol in the striatum

Representative immunostainings of ankG (green; **A1-A3**), ENK (purple; **B1-B3**) and the nuclear counterstain TOPRO (blue; **C1-C3**) in *FOXP1*^{+/-} striatum. Staining with anti-ENK allows the classification to either one of the both pathways: enkephalinergic D1-MSN (white arrow) or DYN-containing D2-MSN. AIS of both indicated by (*). There appears to be no difference in staining quality of the AIS between both cell-types. Scale bar in C1 for A1- C1 = 20 μ m. Scale bar in C3 for A2 – C3 = 20 μ m.

Figure 13: Voltage-gated sodium channels are localized along the AIS

Representative immunostainings of ankG (green; **A1**, **A2**) and Nav1.6 (purple; **B1**, **B2**) in FOXP1^{+/-} striatum. Scale bar in B2 for A and B = 20 μ m. **C**: Co-localisation of voltage-gated sodium channels at the AIS with ankG. Pearson-Correlation, * $P < 0.0001$.

After the protocol was established, the following combination proved to be the most reliable to reproduce for the AIS length analysis in the cortex and striatum: rb anti- β IV-spectrin to indicate the AIS, ms anti-NeuN as a marker for the soma and TO-PRO-3 as a nuclear marker.

4.2 The rodent VPA-model of ASD

4.2.1 AIS length development in S1BF

AIS length has been shown to adapt to altered sensory input and the AIS itself can serve as a sensitive indicator for changes in network state (Jamann et al., 2018). We, therefore, set out to investigate AIS length development and

remodeling in rodent ASD models, which have been associated with altered E/I balance and hence, changes in network activity (Kumamaru et al., 2014). We chose three different time points throughout development: an early postnatal (P3), a juvenile (P15), and an adult stage (P45). These timepoints also coincide with important developmental CPs. At P3, barreloids in VPM are already visible and axon terminals from the thalamus appear in the cortex to form barrel rows (Erzurumlu and Gaspar, 2012). The windows for CP plasticity, following whisker trimming or infra-orbital nerve damage, are beginning to close (end at P4). During the next few days, neurons form the typical barrel patterns in S1BF (Rice and Van der Loos, 1977). Active whisking starts at around P12 (Arakawa and Erzurumlu, 2015; Landers and Zeigler, 2006; Weston et al., 2016). Thus, P15 marks a time point at which sensory input emerges as a driving force for neuronal development. P45 was chosen as a time point at which murine neuronal circuits have reached adulthood (Erzurumlu and Gaspar, 2012; Jamann et al., 2018).

The immunofluorescent staining of the scaffolding protein β IV-spectrin was used to determine the length of the AIS. Length measurements were carried out using AISuite, a self-written software (Ernst et al., 2018; Roos & Engelhardt, unpublished; Rotheneichner et al., 2018; Schlüter et al., 2019). Individual results of AIS length measurements are listed in Table 11.

As outlined in the introduction (2.4.4), AIS in rodent sensory cortices undergo a specific developmental pattern of elongation and shortening (Gutzmann et al., 2014; Jamann et al., 2021). During the early postnatal period, AIS of S1BF pyramidal neurons in layer II/III elongate continuously until the onset of sensory input is thought to initiate a fine-tuning of neuronal excitability which ultimately causes shortening of the AIS to a medium length (Jamann et al., 2021). To analyze, if this pattern was influenced by the exposure of VPA, we plotted AIS length over time (Figure 14, C-F). Indeed, AIS of layer II/III and V of both groups undergo a process of elongation during P3 to P15, then shorten towards a medium length at P45. Differences between the timepoints were almost always significant, except in layer II/III of the VPA group. Here, AIS length was just slightly decreased after P15 (Figure 14, D).

Next, we analyzed if any differences between the medium AIS length between the groups could be found due to the exposure to VPA. The layers of S1BF are interconnected (Aronoff et al., 2010; Erzurumlu and Gaspar, 2012). The first layer to receive input from the thalamus is layer IV. Information is pre-processed, then projected to layer II/III.

Figure 15: Representative immunostaining of layer II/III neurons

Representative immunostainings of pyramidal neurons in S1BF layer II/III at P3, P15 and P45 of NaCl and VPA exposed mice. Staining against NeuN (magenta) and β IV-spectrin (green). Scale bar in F for A-F = 20 μ m.

At first, we analyzed AIS length in layer II/III. At P3, average AIS length was $20.32 \pm 1.91 \mu\text{m}$ (Figure 17) in the VPA-exposed group, and therefore not significantly different to the AIS length measured in controls that presented an average length of $19.08 \pm 0.67 \mu\text{m}$ (One-way ANOVA, $P = 0.3205$; Figure 17, Table 12).

At P15, data showed an average length of $32.57 \pm 1.49 \mu\text{m}$ (Figure 17) in controls. AIS of the VPA group were just slightly, but not significantly shorter

with an average AIS length of $31.53 \pm 4.26 \mu\text{m}$ (One-way ANOVA, $P = 0.5878$; Figure 17, Table 12).

Until adulthood (P45), AIS shortened compared to P15, however, no apparent differences between the groups were observed (NaCl: $30.0 \pm 1.35 \mu\text{m}$; VPA: $28.61 \pm 2.46 \mu\text{m}$; One-way ANOVA, $P = 0.2897$; Figure 17, Table 12).

Figure 16: Representative immunostaining of layer V neurons

Representative immunostainings of pyramidal neurons in S1BF layer V at P3, P15 and P45 of NaCl and VPA exposed mice. Staining against NeuN (magenta) and β IV-spectrin (green). Scale bar in F for A-F = $20\mu\text{m}$.

The aim of this study was to investigate changes of the cortico-thalamical loop after VPA exposure, consequently subsequent processing steps had to be analyzed. After being processed in layer II/III, signals are propagated onto layer

V neurons. From there, information is passed over to subcortical structures involved in action planning and movements such as the thalamus and basal ganglia. Therefore, AIS length was analyzed in layer V next.

Interestingly, differences between both groups were observed in layer V after the juvenile age. First at P3, average AIS length was $20.66 \pm 3.37 \mu\text{m}$ in the NaCl group. AIS length in the VPA group was not different at an average of $20.52 \pm 2.37 \mu\text{m}$ (One-way ANOVA, $P = 0.9308$; Figure 17, Table 12). A tendency of AIS shortening in VPA neurons was seen following P15. AIS of the control group had an average length of $35.68 \pm 2.83 \mu\text{m}$ (Table 12) while AIS of the VPA group were significantly shorter, presenting an average length at $30.17 \pm 2.77 \mu\text{m}$ (One-way ANOVA, $**P = 0.0067$; Figure 17, Table 12).

In adult mice, where cortical circuits have been established and AIS are fully developed, the differences between both groups still exist, although they become smaller (NaCl: $26.14 \pm 1.19 \mu\text{m}$; VPA: $23.99 \pm 1.67 \mu\text{m}$; One-way ANOVA, $*P = 0.0396$; Figure 17, Table 12).

Figure 17: VPA-exposed layer V neurons show AIS remodeling after VPA exposure

AIS length analysis of Layer II/III (A) and layer V (B) neurons during development. Layer II/III pyramidal neurons show no length change after VPA exposure. AIS of neurons in VPA treated mice at P15 and P45 are significantly shorter in layer V compared to controls. One-way ANOVA, $n = 6$, min. 100 AIS/animal, $*P < 0.05$, $**P < 0.01$.

4.2.2 VPA treatment has no effect on axo-axonic innervation patterns in II/III of S1BF

The imbalance of inhibition and excitation is discussed to be one of the main reasons contributing to the development of ASD (Goncalves et al., 2017). Since the innervation patterns specifically localized at the AIS is of importance for the control of input/output parameters, we therefore set out to analyze the axo-axonic innervation pattern in layer II/III pyramidal cells in adult S1BF (P45).

Quadruple immunostaining was applied to enable visualization of complete GABAergic synapses at the AIS. AnkG (ms, ALEXA-405) was used for staining of the AIS, NeuN (ms, ALEXA-647) for the soma, VGAT (rb, ALEXA-568) as a presynaptic marker and GABA_AR_{α2} (gp, ALEXA-488) to stain the postsynapse (Figure 19 A). Images were then deconvoluted and AIS reconstructed using IMARIS, to create 3D models of the AIS. This allowed for an accurate and manual quantification of synapses that were located along the AIS of individual neurons.

For layer II/III, a total of 83 AIS per group were reconstructed and the number of synapses at the AIS manually counted. VPA-exposed mice showed approximately 11 GABAergic synapses per AIS and a higher variation (10.8 ± 5.1) than those of the control group that displayed 9 synapses per AIS (9.3 ± 3.8). The minimum number of synapses counted per AIS was 2, the maximum number was higher in the VPA group (23) than in the control group (19). However, in statistical analysis, no significant differences were found to exist between the groups (unpaired *t*-test, $P = 0.092$; Figure 18).

Figure 18: The GABAergic innervation pattern remains unchanged

A- E: Representative immunostainings of layer II/III mouse S1BF. Staining against βIV-spectrin as a marker for the AIS (green; A), NeuN as a neuronal marker (magenta; B), GABA_ARα₂ as a postsynaptic marker (red; C) and VGAT as a presynaptic marker (blue; D). Scale Bar = 20 μm. Scale Bar in D for A-D. **F:** Representative image of 3D reconstruction of an AIS with IMARIS software. AnkG (red) marks the AIS, GABA_ARα₂ (green) the postsynapse and VGAT (blue) the presynapse. Scale bar = 1 μm. The pictures show the same AIS from different rotation angles (45°, 0°, 90°) **G:** No difference between the number of inhibitory synapses located at the AIS in layer II/III. Bars indicating 5.- 95.%. *t*-test, n=3 animals, 83 AIS/group.

4.2.3 The protein expression profile of ankG does not reflect the developmental AIS length increase

After AIS length changes were observed, we investigated if the increase in AIS length was mirrored by an upregulation of ankG isoforms and βIV-spectrin in S1BF lysates derived from P3 (Figure 19), P15 (Figure 20) and P45 mice (Figure 21). Additionally, protein expression of sodium channels (using a pan anti-Nav antibody) was analyzed, as these channels have direct functional implications for neuronal function. Western blot analysis at P3 was conducted using whole cortical samples to ensure sufficient amounts of material. For P15 and P45 samples, S1 was dissected and separated from the other tissue. Actin was used as an internal loading control to relate protein sample concentrations.

Representative immunoblot bands are shown in Figure 20. Although the length of the AIS shortens from P15 until P45 (compare Figure 17), the expression of β IV-spectrin was not reduced over time (Figure 20, Figure 21, Table 14).

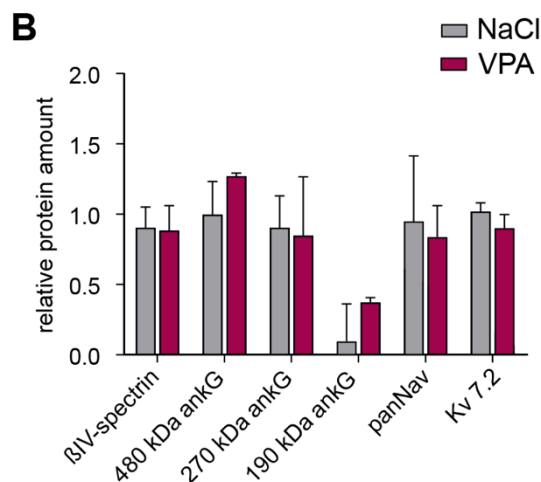

Figure 19: Protein expression pattern remain unaltered at P3

Representative Immunoblots for panNav_v, β IV-spectrin actin (**A**) and ankG (**B**) in VPA-exposed and control mice at P3. Western blot showed antibody-specific bands at approximately 480, 460 and 190kDa for ankG, 260kDa for panNav_v, 140kDa for β IV-spectrin, 60kDa for Kv7.2 and 40kDa for Actin. Quantification of β IV-spectrin, ankG, panNav_v and β IV-spectrin (**C**). Fluorescent intensity was normalized to the intensity of the internal loading control (Actin). At P3 no significant differences between protein expression levels were found. One-way ANOVA, n=3-6 animals. Mean values from three technical replicates.

At P15, expression profiles of the three ankG isoforms were similar in both groups (Figure 20). In the NaCl group, only the giant isoform (480 kDa) was reduced at P45 compared to earlier stages (Figure 21, Table 14). Contrary to what was hypothesized, protein expression of ankG in the VPA group was slightly higher compared to controls at any time point. Additionally, ankG protein expression increased, although a reduction was to be expected considering that overall, AIS length decreased after P15 (Figure 17).

Figure 20: Protein expression of sodium channels is slightly enhanced at P15 in VPA-exposed mice

Representative immunoblots for panNav_v, βIV-spectrin, actin (**A**) and ankG (**B**) of VPA-exposed and control mice at P15. Western blot showed antibody-specific bands at approximately 480, 270 and 190kDa for ankG, 260kDa for panNav_v, 140 kDa for βIV-spectrin and 40kDa for Actin. Quantification of ankG, panNav_v and βIV-spectrin (**C**). Fluorescent intensity was normalized to the intensity of the internal loading control (Actin). At P15 the level of βIV-spectrin was reduced in the NaCl-group. One-way ANOVA; n=3-6 animals. Mean values form three technical replicates.

Voltage-gated sodium channels that are enriched at the AIS and at noR are critical for AP generation (Kole et al., 2008) Therefore, the shortening of the AIS could result in a reduction of sodium channel expression. Protein expression of all sodium channels (panNav_v) was slightly, but not significantly, reduced in controls at P15 (One-way ANOVA, $P = 0.1277$; Figure 20; Table 14). At P45, protein expression was then reduced in VPA mice, but again, this effect was not statistically significant (One-way ANOVA, $P = 0.1184$, Figure 21; Table 14).

Figure 21: VPA exposure does not alter protein expression levels in adult stages (P45)

Representative immunoblots for panNav, β IV-spectrin, actin (**A**) and ankG (**B**) of VPA-exposed and control mice at P45. Western blot showed antibody-specific bands at approximately 480 and 190kDa for ankG, 260kDa for panNav, 140 kDa for β IV-spectrin and 40kDa for Actin. Quantification of ankG, panNav and β IV-spectrin (**C**). Fluorescent intensity was normalized to the intensity of the internal loading control (Actin). At P45 no significant differences between protein expression levels were found. One-way ANOVA; n=3-6 animals. Mean values from three technical replicates.

Overall, changes of AIS length could not be correlated to the protein expression of ankG and β IV-spectrin. Protein expression was always slightly higher in VPA mice compared to control mice; however, no significant differences could be detected at any time point. However, some confounding factors regarding the determination of protein expression in those samples have to be considered. As ankG is not only present at the AIS, but also at noR and spines, protein expression is therefore influenced by changes of myelination and synapse formation (Jenkins et al., 2015; Smith et al., 2014; see section 5.1). Similarly, the panNav antibody detects all Navs in any given sample, and since the somatodendritic domain is heavily endowed with these channels, more subtle changes at the AIS could well be masked. Additionally, cortical layers were not separated in this study. Conclusions about layer-specific changes are therefore not possible.

4.3 Electrophysiology

Changes in AIS length can result in changes of neuronal excitability (Jamann et al., 2021; Kuba et al., 2010). A pyramidal cell with a longer AIS therefore should be more excitable by showing a reduced AP threshold and vice versa, a pyramidal cell with a shorter AIS presents a higher AP threshold and is therefore less excitable. In order to test if the influence of VPA exposure on AIS length shows electrophysiological correlations, we conducted whole-cell patch-clamp recordings in pyramidal neurons of S1BF layer II/III and layer V. Acute slices of mice at P15 (± 2 days) were prepared and active and passive properties were analyzed. All electrophysiological data are presented in Table 15 and 16.

Figure 22: Staining protocol for post-hoc immunofluorescence of electrophysiological recordings

A-C: Representative immunostaining of layer II/III neurons of VPA-exposed mice. The cell, which was used for patch-clamp recordings was filled with biocytin during measurements. Branches of the dendritic tree extend into layer I. Biocytin as a marker for the cell soma of the recorded neuron, β IV-spectrin to mark the AIS. NeuN was used as a marker for all other neurons. Scale bars indicating 20 μ m. **D-F:** Close-up of the Neuron (from A) with its corresponding AIS (arrow). Scale Bar in D for D-F, indicating 10 μ m.

4.3.1 Active and passive properties of S1BF layer II/III remained unchanged after VPA exposure

Data show that resting membrane potential (RMP) was approximately -80mV in both groups (Figure 24 D; NaCl: -81.44 ± 5.86 mV; VPA: -80.86 ± 6.84 mV; unpaired *t*-test, $P = 0.8639$) and series resistance also remained unchanged after VPA exposure (Table 15; NaCl: 242.5 ± 105.4 M Ω ; VPA: 298.6 ± 95.95

MΩ, unpaired *t*-test, $P = 0.3147$). To measure active properties, the membrane potential was held at 0 A in current-clamp mode. AP threshold was defined at the first step of a series of depolarizing current steps of 20 ms duration that produced an AP. AP properties were analyzed in the first AP elicited in current-clamp mode. We found no differences in neither AP half-width (Figure 23 B; NaCl: 3.599 ± 0.759 ms; VPA: 3.221 ± 0.903 ms, unpaired *t*-test, $P = 0.3955$), AP amplitude (Figure 23 B; NaCl: 104.3 ± 11.8 mV; VPA: 102.2 ± 4.86 mV, unpaired *t*-test, $P = 0.6956$) nor the maximum AP firing frequency (Figure 23 F; Table 15). Furthermore, VPA-exposure had no impact on neither current (NaCl: 189.7 ± 45.77 pA; VPA: 232.6 ± 133.6 pA, unpaired *t*-test, $P = 0.4124$) nor voltage threshold to elicit APs (Figure 23 C; Table 15; NaCl: -56.68 ± 5.48 mV; VPA: -54.55 ± 5.328 mV, unpaired *t*-test, $P = 0.4683$). Regarding AP kinetics, analysis of the slopes (dV/dt) revealed that upstroke and repolarization were similar between both groups. Representative phase plane plots are presented in Figure 23 E (Table 15; for AIS peak: NaCl: 89.82 V/s; VPA: 89.23 ± 30.41 V/s, unpaired *t*-tests, $P = 0.9694$; for soma peak: NaCl: 212.6 ± 77.83 V/s; VPA: 174.2 ± 60.4 V/s, unpaired *t*-tests, $P = 0.3274$).

Cells of the VPA group produced repeating AP trains at lower input currents, although firing frequency adapted to being similar to the control group without presenting any significant differences between the current steps (Figure 23 F). In order to control and identify the correct layer of the location of the neuron as well as to confirm the cell type, we performed post-hoc immunostaining, using the biocytin fill as a marker of the pyramidal cell and antibodies against β IV-spectrin to stain the AIS (Figure 22). According to the results of AIS length measurements in layer II/III that showed no differences between VPA-exposed and control animals, passive and active electrophysiological properties were unchanged.

Figure 23: Electrophysiological recordings reveal no changes in layer II/III

A: Representative traces of single APs of NaCl (grey) and VPA (red) neurons elicited by 20ms current injections. 10pA increments were applied to determine current threshold. No differences between both groups were seen. **B:** Statistical analysis of passive AP parameters: Neither AP amplitude nor AP half showed significant differences. **C:** Statistical analysis of Current and Voltage threshold, RMP (**D**) and membrane resistance (**D**). **E:** Phase plane plot analysis of NaCl (grey) and VPA-exposed (red) neurons. Left: Representative phase plane plots of NaCl and VPA neurons indicate similarities in AP shape. Right: Analysis of the first (AIS) and second (soma) peak of the phase plane plots show no significant differences between both groups. **F:** Representative traces of AP trains elicited by increasing current injection steps (500 ms, 50 pA steps). No differences in firing frequency were detected in layer II/III neurons. **G:** Input/frequency relationship determined by the application of increasing current steps of 50 pA under a duration of 500 ms. Two-way ANOVA for current injection, group and interaction, Table 17.

4.3.2 VPA-exposure alters active properties of Layer V neurons

In contrast to layer II/III, where no differences regarding AIS length and correlating electrophysiological properties of the neurons were found, AIS length measurements in layer V indicated shortening of AIS length due to the exposure of VPA. Based on current biophysical theory, shorter AIS as seen in the VPA group, should result in decreased neuronal excitability (Goethals and Brette, 2020; Figure 17). We therefore tested whether this holds true in our model by performing whole-cell patch-clamp recordings in layer V neurons of S1BF.

Passive properties remained unchanged between groups. Neither resting membrane potential nor series resistance showed any differences (unpaired *t*-tests; $P = 0.622$; $P = 0.6437$, respectively, Figure 24 D, Table 16).

Interestingly, AP shape and kinetics seemed to be influenced by VPA-exposure. AP half-width was found to be reduced significantly in VPA-treated mice (NaCl: 5.615 ± 0.433 ms; VPA: 4.595 ± 0.491 ms; unpaired *t*-test, $***P < 0.0001$), indicating faster upstroke and repolarization in those neurons. This agrees with the analysis of AP slopes, showing that both AIS peak and soma peak are faster in the VPA group (Figure 24 E, Table; unpaired *t*-test; $**P = 0.0070$; $*P = 0.0478$). The current and voltage threshold to elicit APs were not different (unpaired *t*-test, $P = 0.6867$; $P = 0.5587$, respectively; Figure 24 C, Table 16).

Additionally, we observed that pyramidal cells of the VPA group could sustain repetitive firing upon the injection of higher input current; however, the maximum firing frequency did not differ between both groups (Figure 24 F, G; Two-way ANOVA for current injection, group and interaction, Table 17).

Figure 24: Electrophysiological properties of layer V neurons in S1BF are altered after VPA exposure

A: Representative traces of single APs of NaCl (grey) and VPA (blue) neurons elicited by 20ms current injections. 10pA increments were applied to determine current threshold. No differences between both groups were seen. **B:** Statistical analysis of passive AP parameters: AP amplitude remained unchanged, but the AP half width of VPA-exposed mice was significantly decreased. **C:** Statistical analysis of Current and Voltage threshold, RMP (**D**) and membrane resistance (**D**). **E:** Phase plane plot analysis of NaCl (grey) and VPA-exposed (blue) neurons. Left: Representative phase plane plots of NaCl and VPA neurons indicate differences in AP shape, indicating a faster upstroke/repolarization in VPA-neurons. Right: Analysis of the first (AIS) and second (soma) peak of the phase plane plots shows significant differences between both groups in both regards. **F:** Representative traces of AP trains elicited by increasing current injection steps (500 ms; 50 pA steps). No differences in firing frequency were detected in layer II/III neurons. **G:** Input/frequency relationship determined by the application of increasing current steps of 50 pA under a duration of 500 ms. Two-way ANOVA, multiple comparisons for current injection, group and interaction, Table 17.

4.3.3 VPA-exposure influences AIS length in the adult dorso-lateral striatum

Layer V of S1BF projects to the basal ganglia, mainly to the dorsolateral part of the striatum. After data showed that VPA exposure had an influence on AIS development in layer V of S1BF, we investigated if those changes influence downstream regions in the cortico-thalamical loop. Cryosections of the striatum from VPA-exposed and controls at P15 and P45 were stained for confocal microscopy, after the staining protocol was established (Chapter 4.1.). The dorsal striatum can be roughly divided into a medial and a lateral part based on different inputs and outputs. Overlapping areas make it difficult to draw a strict border between those two groups. Therefore, AIS were assigned to one of the groups based on their location within the striatum. Figure 25 gives a schematic overview of the classification of the dorso-lateral (DLS) and the dorso-medial striatum (and DMS).

Figure 25: Schematic classification of the dorsal striatum in DLS and DMS

Schematic representations of transvers sections taken at -0.22mm (A) and -0.58mm from bregma (B), allowing the approximate allocation to one of the 4 main sections of the striatum: dorso-lateral (DL), dorso-medial (DM), ventro-lateral (VL) and ventro-medial (VM). Scale Bar = $1\ \mu\text{m}$. Figures modified after (Paxinos and Franklin, 2019).

We evaluated a possible influence of VPA exposure on the main striatal neuron type, GABAergic medium spiny neurons, so called spiny projection neurons (SPN) in the DLS.

At P15, AIS of the VPA group showed no difference compared to controls (*t*-test, $P = 0.5862$; Figure 26). While VPA exposure caused a reduction of AIS length in layer V at this time-point, the effect was reversed in the striatum. Here, medium length in the control group was $22.93 \pm 1.61 \mu\text{m}$, therefore, shorter, but not significantly, than AIS of the VPA-exposed group ($23.57 \pm 2.02 \mu\text{m}$, unpaired *t*-test, $P = 0.5862$, Figure 26)

VPA exposure had the same effect at later ages. At P45, the mean AIS length of the experimental group ($24.62 \pm 1.375 \mu\text{m}$) was longer than of the control group ($22.57 \pm 1.259 \mu\text{m}$; unpaired *t*-test, $*P = 0.0389$; Figure 26). Significant differences were only seen in the DLS in adult mice.

The tri-phasic development of AIS length that has been reported in visual and somatosensory cortices apparently does not apply for all areas of the rodent brain. We next asked whether AIS of the striatal MSN undergo a similar developmental process as seen in S1BF, and if so, if this length development over time was influenced by VPA exposure. In the control group, the typical shortening of AIS during the timespan from P15 up to P45 was only vaguely seen (from $22.93 \pm 1.61 \mu\text{m}$ (P15) to $22.57 \pm 1.259 \mu\text{m}$ (P45)). Interestingly, in the VPA group, AIS continued to lengthen during that period (from $23.57 \pm 2.02 \mu\text{m}$ (P15) to $24.62 \pm 1.375 \mu\text{m}$ (P45)). Differences between time-point were not statistically significant in any group.

Finally, the data was plotted in size frequency histograms. Data revealed no apparent differences at P15 Kolmogorov-Smirnoff-test; $P = 0.3676$; Figure 26). AIS length was homogenously distributed in the DLS of both groups. At P45, AIS length in the control group was less scattered and more concentrated towards the medium length at approximately $23 \mu\text{m}$ whereas AIS length in the VPA group remained more heterogeneous (Kolmogorov-Smirnoff-test, $*P = 0.0103$; Figure 26).

Figure 26: AIS length development in the striatum

A: Representative immunostaining images of DLS and DMS of VPA-exposed and control mice at P45 (AIS = green, soma = purple). **B:** AIS length frequency distribution histograms of DLS in NaCl and VPA. No differences in length distribution were seen at the juvenile time point (P15), but in the adult (P45). Kolmogorov-Smirnoff test, $*P < 0.05$. **C:** AIS length analysis of DLS at P15 and P45. At P15 no differences between both groups were found. At P45 AIS of neurons in VPA treated mice in the DLS are significantly longer compared to controls. MSN in the DMS show no length change after VPA exposure (data not shown here). *t*-test, $n=6$, at least 100AIS/animal, $*P < 0.05$. **D:** Representative immunostainings of MSN of the adult DLS. (AIS = green, soma = purple). Scale bar = 20 μ m.

4.3.4 Western blot analysis in the striatum showed similar protein expression patterns between VPA-exposed and control groups

As in the cortex, a possible correlation between the length of the AIS and the protein expression of the scaffolding proteins ankG and β IV-spectrin was measured in the striatum. Again, actin was used as an internal loading control to relate protein sample concentrations. No differences between the groups were seen regarding the protein expression patterns of β IV-spectrin at P15, although it was elevated in the VPA-group (Figure 27). This agrees with the results of the AIS length analysis, where no significant differences, just tendencies were detected. In the adult brain (P45), again no differences between the VPA and control-group could be found. However, the protein expression of β IV-spectrin decreased over time, which is in accordance with the decreasing length of the AIS during that time period.

At P15 protein expression of all isoforms of ankG was slightly enhanced in VPA mice although not statistically significant (Figure 27, One-way ANOVA, $P = 0.8531$ (480 kDa); $P = 0.9646$ (270 kDa); $P = 0.6003$ (190 kDa). This tendency remained until P45, (Figure 27; unpaired t -test, $P = 0.3762$ (190 kDa)).

Apart from structural proteins, expression of sodium channels was investigated. We conducted Western blot analysis of voltage-gated sodium channels (anti-panNav antibody) of striatal samples at P15 and P45. Here, data indicated no significant changes in protein expression between the groups (Figure 27; One-way ANOVA, $P = 0.5527$ (P15); $P = 0.3103$ (P45)).

Next, we measured protein expression patterns of the transcription factor FOXP1. FOXP1 has been implicated in the pathogenesis of ASD and is strongly expressed in the striatum. Although differences between VPA-exposed and control mice were not statistically significant, protein amount of FOXP1 at P15 seemed slightly reduced in striatum of VPA-exposed mice (Figure 27; One-way ANOVA, $P = 0.977$). This could present one possible commonality between the two ASD-models investigated in this study (see discussion section 5.8).

Figure 27: Protein expression levels are unaltered in the rodent striatum

Representative immunoblot bands for panNav, βIV-spectrin, and actin of VPA-exposed and control mice at P15 (**A**) and P45 (**B**). Western blot showed antibody-specific bands at approximately 260 kDa for panNav, 140 kDa for βIV-spectrin, and at 40kDa for actin.

Quantification of panNav, βIV-spectrin at P15 (**C**) and P45 (**D**) was normalized to the internal loading control (actin). No differences between protein expression levels of panNav and βIV-spectrin were found at P15 (**A; C**) and P45 (**B; D**). One-way ANOVA, * $P < 0.05$; $n = 3$ animals. Mean values from three technical replicates.

4.4 The FOXP1-heterozygous model of autism

After we investigated structural and electrophysiological changes in the VPA-model of autism, we set out to investigate a genetic mouse model of autism. FOXP1^{-/-} mice show similar symptoms as mice that were exposed to valproate (an overview is given in Table 10). These symptoms include functional and morphological changes in S1BF and basal ganglia. FOXP1^{-/-} mice die at around E14.5 due to severe cardiac abnormalities (Wang et al., 2004). As we were looking for a model to investigate developmental changes until adulthood, the FOXP1^{+/-} model seemed more suitable for this purpose, as animals show just slight abnormalities in cognitive and motor function but are otherwise viable (Anderson et al., 2020; Co et al., 2020).

4.4.1 FOXP1 is robustly expressed in striatal and thalamic regions and cortical layers

To visualize the expression profile of FOXP1 in the brain of wildtype adult mice, we performed FOXP1 immunohistochemistry. Staining of slices against anti-FOXP1 indicated robust protein expression in cortical layers II/III, with less expression in infragranular layers. Strong expression was further seen throughout various regions of the striatum and thalamic nuclei (Figure 28). These results confirmed previous data (Ferland et al., 2003; Hisaoka et al., 2010).

Figure 28: FOXP1 expression profile in the adult mouse brain

Representative images of FOXP1 immunohistochemistry in FOXP1^{+/+} (A) and FOXP1^{+/-} (B) at different locations throughout the dorsal striatum. Strong expression of FOXP1 is seen in layer II/III, layer V and striatal regions in both genotypes. Scale Bar in B for A-B = 1 μ m.

4.4.2 The striatal area is not reduced in FOXP1^{+/-} compared to controls

FOXP1^{-/-} mice were reported to show gross morphological abnormalities including a prominent reduction of the striatal area (Bacon et al., 2015). To determine if the FOXP1^{+/-} genotype has the same effect regarding basal ganglia morphology, we performed immunohistochemistry directed against the Ca²⁺-binding protein calbindin, to label all medium sized SPN in the striatum (Prensa et al., 1998) and against Tyrosine-Hydroxylase (TH) to visualize dopaminergic neurons. As the different subregions of the dorsal (DMS, DLS) and ventral striatum cannot be strictly distinguished, total striatal area was quantified. The striatal area was defined as area with TH-positive staining. The striatal area measured in FOXP1^{+/+} (0.12 ± 0.42 mm²) showed no statistically significant difference to the area measured in FOXP1^{+/-} animals (Figure 29; 0.12 ± 0.2 mm²; unpaired *t*-test, $P = 0.9804$). Hence, FOXP1 heterogeneity is not as disruptive as a complete knock-down of FOXP1.

A FOXP1^{+/-} (anti-TH)**Figure 29: Quantification of the striatal area in FOXP1^{+/-} and FOXP1^{+/+} mice**

Representative image of tyrosin-hydroxylase (TH) immunohistochemistry in FOXP1^{+/-}. Scale Bar = 1 μ m.

B: Boxplot of the quantified striatal area in FOXP1^{+/-} and FOXP1^{+/+} mice. Bregma 1.42mm to -2.06 (Franklin and Paxinos, 2013). N= 7 FOXP1^{+/-}, n=5 FOXP1^{+/+}. Whiskers indicating SD.

4.4.3 AIS are shortened in the dorsal striatum of FOXP1^{+/-} mice

Abnormal striatal function is suggested to be one of the foundations of altered behavioral patterns in ASD (Araujo et al., 2015). After changes of AIS length in the DLS were found in the VPA model, we investigated possible changes in the dorsal striatum of FOXP1^{+/-} mice. To do so, slices were stained for confocal microscopy, using the established staining protocol (section 3.2). AIS were assigned to the DMS or DLS, depending on the location of the image taken. The analysis was conducted using the same method as described above. We found no differences between both groups in the DMS. Here, mean AIS length in FOXP1^{+/-} was $21.43 \pm 5.725 \mu\text{m}$, which is not statistically different from the mean AIS length in FOXP1^{+/+} ($21.75 \pm 5.375 \mu\text{m}$; unpaired *t*-test, $P = 0.3454$; Figure 30; Table19).

Data shows that differences between both groups appear in the DLS. AIS are significantly shorter in the DLS of FOXP1^{+/-} (21.74 ± 1.83 μm) compared to controls (22.75 ± 5.65 μm; unpaired *t*-test, *P* = 0.0398; Figure 30, Table 18). Similar to the results in the VPA model, the influence of reduced FOXP1 during periods of AIS maturation seems to impact MSN in the DLS. Plotting the individual AIS in size distribution histograms showed no difference between both groups in neither of the areas that were analyzed (Kolmogorov-Smirnoff-test; *P* = 0.2192 (DLS), *P* = 0.1985 (DMS); Figure 30; Table 20).

Figure 30: AIS length is decreased in DLS of FOXP1^{+/-} mice

A: Representative immunostainings in DLS and DMS in FOXP1^{+/+} and FOXP1^{+/-} mice. **B:** AIS length distribution in DLS of FOXP1^{+/+} (grey) and FOXP1^{+/-} (green) mice. **C:** AIS in FOXP1^{+/-} mice are significantly shorter in DLS compared to controls. *T*-test, **P*<0.05. AIS are plotted as individual data points. Bregma 0.14 mm to -0.82 mm. **D:** AIS length distribution in DMS of FOXP1^{+/+} (grey) and FOXP1^{+/-} (green) mice. **E:** No differences were found in the DMS when comparing both groups. *T*-test, **P*<0.05. AIS are plotted as individual data points. Bregma 0.14 mm to -0.82 mm. **F:** Male: n= 2 FOXP1^{+/-}, n= 3 FOXP1^{+/+}, min. 100 AIS/each. Female: n= 5 FOXP1^{+/-}, n=2 FOXP1^{+/+}, min. 100 AIS/each. *T*-test, **P*<0.05. AIS are plotted as individual data points.

4.4.4 AIS remodeling is pronounced in male FOXP1^{+/-} mice

ASD shows a strong bias towards the male sex (Hara et al., 2012). Underlying causes are still under debate. Males are said to be more exposed to elevated fetal testosterone levels, whereas females are said to have a higher genetic burden towards autism (James and Grech, 2019). Regardless of the origin, morphological changes or differences between both genders have not been investigated in greater detail. Therefore, we evaluated whether differences regarding AIS length could be observed for the different genders.

Considering the results of all animals regardless of their gender, AIS length was shortened in the striatum of FOXP1^{+/-}. When the group was divided by sex, this effect was still seen, however, enhanced in the male group. AIS length in FOXP1^{+/-} male mice ($21.37 \pm 5.705 \mu\text{m}$) was significantly shorter than in FOXP1^{+/+} males ($23.33 \pm 5.548 \mu\text{m}$; unpaired *t*-test, $**P < 0.001$; Figure 30). In females, the difference between both groups is still significant (unpaired *t*-test, $*P = 0.0136$; Figure 30), but in contrast to the results seen in males. Here, AIS of FOXP1^{+/-} females ($21.96 \pm 5.83 \mu\text{m}$) were longer than those of the controls ($21.18 \pm 5.32 \mu\text{m}$, unpaired *t*-test, $*P = 0.0136$).

If these pronounced differences in males are causal or consequences of other alterations has to be investigated further.

It must be taken into consideration that the number of experimental animals was less than 3 in some of the groups when divided by gender. Therefore, these results have to be interpreted cautiously.

4.4.5 Western blot analysis suggests downregulation of voltage-gated ion channel expression in Foxp1^{+/-} mice

After changes regarding AIS length were discovered, expression of AIS associated proteins was measured in FOXP1^{+/-} animals to investigate whether they correlate with the histological analysis.

Protein expression of ankG isoforms was analyzed using whole-brain samples from adult FOXP1^{+/-} and FOP1^{+/+} mice. Furthermore, protein expression

patterns of sodium and potassium channels were investigated. As previously described in section 4.2.3, actin was used as an internal loading control.

As expected, protein expression of FOXP1 in FOXP1^{+/-} mice was reduced by half compared to FOXP1^{+/+} (One-way ANOVA, **P* = 0.0372; Figure 31 C).

No difference was detected in protein expression of ankG isoforms (Figure 31; Table 21).

Confounding factors of immunoblot analysis have been briefly mentioned before (see section 4.2.3) and are thoroughly discussed in section 5.1. Any changes to striatal ankG expression due to the FOXP1 phenotype could therefore easily be masked by the total amount of neuronal ankG in the sample (Figure 31).

Protein expression of Navs was significantly reduced in FOXP1^{+/-} mice compared to FOXP1^{+/+}. The relative protein expression of sodium channels detected in FOXP1^{+/+} was more than double the amount detected in FOXP1^{+/-} (One-way ANOVA, **P* = 0.0169; Figure 31). Likewise, potassium channel (KCNQ2) protein expression was also significantly reduced in FOXP1^{+/-} (One-way ANOVA, **P* = 0.0316; Figure 31). Individual statistical results are listed in Table 21.

Consequently, reduced protein expression of ion channels could be one indicator of altered network state in the FOXP1^{+/-} model of autism.

Figure 31: FOXP1^{+/-} mice show significant reduction in Na⁺- and K⁺ channels

Representative immunoblots for ankG, FOXP1, panNav_v, and actin of FOXP1^{+/-} and FOXP1^{+/+} mice in striatum (**A**) Western blot showed antibody-specific bands at approximately 480 kDa and 190 kDa for ankG, at 80 kDa for FOXP1, 270 kDa for panNav_v and at 40 kDa for actin. **C**: Quantification of FOXP1, ankG, panNav_v, and KCNQ2 was normalized to the internal loading control (actin). Significant differences between the protein levels of FOXP1, panNav_v and KCNQ2 were found in striatal samples One-way ANOVA, **P*<0.05. Whiskers indicating SD. N=3 animals. Mean values form three technical replicates.

5 DISCUSSION

5.1 Methodical and statistical considerations

As previously outlined, the AIS is a highly plastic microdomain able to adapt several geometrical parameters such as length and location depending on network state (reviewed in (Jamann et al., 2018)). Considering AIS maturation and homeostatic plasticity, several aspects are analyzed in this thesis. AIS length is an indicator for neuronal excitability, as it has been shown that longer AIS are more excitable than shorter AIS and elicit APs more easily (Kuba, 2010). Therefore, in this thesis, AIS length is the primary focus of all analyses.

To increase the predictive significance of AIS length measurements, almost 10.000 single AIS were analyzed in this study. Of note each single neuron plays its individual role in a locally defined neuronal network, with putatively far-reaching consequences. Interestingly, single values of AIS length indicate a significant variance even across similar cell types, a fact noted previously in numerous studies (Höfflin et al., 2017; Kole and Brette, 2018; Thome et al., 2014). So, in order to account for this AIS length and location heterogeneity, at least 100 AIS from a defined region of interest were measured per animal; statistical analysis was then performed of the mean values of the individuals.

Voltage-gated ion channels are fundamental to neuronal excitability. Sodium and potassium currents are required for shaping APs (Goldberg et al., 2008; Hu et al., 2009; Kole et al., 2007). Therefore, protein expression patterns of those were evaluated via Western blot quantification. Furthermore, the AIS scaffolding proteins ankG and β IV-spectrin, which serve as the backbone of the histological and morphometrical analysis of AIS length, were also used in immunoblots in this study.

Due to technical and anatomical limitations, especially during early postnatal stages, it was not always possible to separate the regions of interest, i.e., the striatum and the S1BF, from surrounding brain tissue. Therefore, conclusions based on protein expression profiles in this study have to be considered in light

of the fact that anatomical regions may be mixed. One might conclude that AIS length and thus protein expression could correlate to the total amount of protein in the sample.

However, it is important to point out that ankG is expressed outside of the AIS quite abundantly, either in the somatodendritic domain or noR. Especially regarding noRs, the ongoing process of myelination after P15 could lead to an increase of ankG protein expression during that time span (Jenkins et al., 2015; Kordeli et al., 1995). The smaller isoforms of 190kDa and 270kDa are also located at synapses (Smith et al., 2014), the giant isoform can also be found at GABAergic synapses along the dendritic shaft (Tseng et al., 2015). Synapse formation or pruning could therefore impact ankG protein expression (see section 4.2.3.).

5.1.1 Potential and limitations of mouse models

Rodent models are a favored tool to investigate putative underlying molecular, functional, and structural alterations during the development and progressing of neurodevelopmental diseases such as ASD. Whether or not a model is “sufficient” to recreate a specific disease pattern depends on the commonalities between the rodent model and humans. A suitable model must fulfil certain criteria regarding construct, predictive, and face validity. If all criteria are met, the rodent model can be considered as strong. Apparently, no animal model can be valid for all purposes (van der Staay, 2006), as certain criteria only help to evaluate the validity of rodent models for certain situations.

Construct validity describes the etiology of the disorder and the degree of similarity. VPA induces ASD-phenotypes in humans as well as in rodents: it causes oxidative stress, inhibits histone deacetylase, and causes an imbalance of excitation and inhibition in both species (Moore et al., 2000). It is therefore plausible that the phenotype can result from the same background etiology.

Recently, FOXP1 has been placed upon the list of highest-ranked candidate genes for developing ASD (Ayhan and Konopka, 2019). Many gene-interrupting variants, such as heterozygous deletions, duplications, missense and nonsense mutations have been identified in large-scale profiling of patients diagnosed with ASD (Iossifov et al., 2014; Iqbal et al., 2013; Le Fevre et al., 2013; Siper et al., 2017). Deletions of FOXP1 cause language and behavioral impairment in rodent models (Bowers and Konopka, 2012) and in human studies (Siper et al., 2017). Those traits are likely to be associated with FOXP1 haploinsufficiency.

Face validity specifies the disease endophenotype. A model has a strong face validity if it depicts the same observable behavior, the same neuropathology, or neurochemical alterations (Mabunga et al., 2015; Willner, 1984). To render tests and results comparable to humans, rodent phenotypes and behaviors have to be translated into suitable and standardized tests (van der Staay, 2006). Appropriate tests for features of psychological diseases include social recognition or social approach tests (Chadman et al., 2009). Table summarizes examples for disease endophenotypes of both models used in this thesis. Both models show a high level of face validity, as examples for typical autistic phenotypes were observed from various laboratories in the past.

Table 10: Face validity of ASD mouse models

ASD Feature	FOXP1^{+/-}	VPA-exposure
Social interaction	Araujo et al., 2017	Kim et al., 2014 Kim et al., 2011 Schneider and Przewlocki, 2005 Kim et al., 2013 Bambini-Junior et al., 2011 Kataoka et al., 2013 Roullet et al., 2013 Moldrich et al., 2013
Reduced explorations	Araujo et al., 2017 (Bacon et al., 2015)	Kim et al., 2014 Schneider and Przewlocki, 2005

Altered motor coordination		Hou et al., 2018 Schneider et al., 2007
Altered anxiety behavior	(Bacon et al., 2015) (Araujo et al., 2017)	Hou et al., 2018 Kataoka et al., 2013 Schneider et al., 2007

ASD = Autism Spectrum Disorders, VPA = Valproic acid

Lastly, predictive validity describes trigger and response correlations plus treatment responses. Research has just recently advanced to investigate novel treatment options. Current gold-standard of ASD treatment in children remains

psychotherapy and behavioral therapy (Eldevik et al., 2009). This obviously cannot be transferred into rodent models; therefore, this last aspect will remain unconsidered in this thesis.

The majority of patients with ASD were not exposed to VPA *in utero*, nor have a heterozygous deletion or other mutations of FOXP1. Results of this study obviously cannot speak for every disease phenotype or origin of the whole spectrum of disorders.

Furthermore, it seems logical that the timing of human neurodevelopment cannot be directly transferred to animal models and rodent brain development. Comparing important steps in maturation such as the synchronization of spontaneous network activity, helps to place the time-span of P14-P16 to about the time of the third trimester and the earliest postnatal months (Workman et al., 2013).

5.1.2 Implementation of striatal AIS staining protocols

Immunostaining for AIS length measurements has to produce specific and reproducible results. Antibodies against the two main scaffolding proteins ankG and β IV-spectrin have been shown to produce reliable staining results in rodent cortical areas and the hippocampus across a number of studies from independent laboratories (Benedetti et al., 2020; Fréal et al., 2016; Hamada et al., 2016; Höfflin et al., 2017; Huang and Rasband, 2018; Jenkins et al., 2015; Schlüter et al., 2017; Sobotzik et al., 2009). No significant differences between AIS length measurements using either ankG or β IV-spectrin staining have been documented (Gutzmann et al., 2014; Jamann et al., 2021), therefore the antibodies can be used equally well and since they are derived from different species, can be combined with other primary antibodies. Staining protocols for cortical neurons have already been established in our lab (Höfflin et al., 2017; Jamann et al., 2021; Schlüter et al., 2017; Schlüter et al., 2019). Data on striatal samples were not available beforehand.

First, striatal AIS had to be reliably stained. Our results showed no differences between ankG and β IV-spectrin in staining efficiency. This meant, that we were able to use the cortical slices that we had already stained for AIS length analysis of the cortex and use them again for confocal microscopy of the striatum. This helped to reduce resources and animal number.

Likewise, immunostaining of sodium channels in striatal SPN was successfully established. We confirmed previous data with notable colocalization of Nav1.6 at the AIS (Akin et al., 2015; Solé and Tamkun, 2020; Wimmer et al., 2015; Figure 13).

Lastly, we asked whether AIS of D1 and D2 SPN could equally be recognized by our antibodies. D1 positive SPN contain ENK, which we used to stain for neurons of the direct pathway. As Figure 12 shows, AIS in both types were stained and could be used for analysis.

FOXP1 is equally expressed in the striosome and matrix of the rodent basal ganglia (Takahashi et al., 2003), as well as in D1 and D2 SPN (Fong et al., 2018). This uniform distribution suggests that FOXP1 haploinsufficiency has the same effect on both pathways. Note, while FOXP1 is observed in over two thirds of striatal matrix projection neurons, it was not detected in interneurons. Any influences of FOXP1 seem to exclusively impact projection neurons (Tamura et al., 2004).

Maternal VPA treatment seems to have a different effect on striosomal neurons, most likely due to the fact that exposure at E13 coincides with the critical period of striosomal neurogenesis (Kuo and Liu, 2017). Aberrant development of striatal compartments and pathways with reduced numbers of corticostriatal synapses were observed in the rostral striatum in mice (Kuo and Liu, 2017) but also in humans (Kuo and Liu, 2020). Interestingly, FOXP2-positive neurons were decreased in layer VI, but increased in layer V, which projects to the basal ganglia. The effect of VPA on FOXP1-positive neurons has not been further investigated.

While starting with the first AIS length measurements in this study, the aim was to gain an overview of general striatal AIS development. Therefore, results were not differentiated between the direct and indirect pathways. Different

combinations of antibodies, that could help to distinguish between D1 and D2 positive neurons and their affiliated AIS were already tested in the laboratory and could provide the basis for further investigation in this regard.

5.2 Differential effects of VPA-exposure on supra- and infragranular neurons in S1BF

In this thesis, we identified structural AIS remodeling in two mouse models of ASD, which also correlated with distinct changes in the input/output properties of neurons. Interestingly, these changes were confined to infragranular layers in S1BF, while supragranular neurons were largely unaffected by VPA exposure. Specifically (1) AIS plasticity after VPA exposure was not detected in layer II/III of S1BF, (2) electrophysiological properties remained unchanged accordingly, (3) the axo-axonic innervation pattern showed no significant differences and (4) VPA exposure is not disruptive enough to remove the distinct tri-phasic developmental pattern of AIS length in somatosensory cortices.

On contrast, analysis of layer V neurons in S1BF demonstrated that (1) AIS of layer V in S1BF adapted to VPA-exposure by a significant length decrease, (2) AP properties of layer V cortical neurons were changed and (3) in DLS, AIS of SPN were elongated compared to controls.

5.3 The effect of VPA-exposure on the rodent whisker-to-barrel system

In order to evaluate the validity of a rodent model to investigate changes due to VPA-exposure, similarities and differences of the somatosensory circuit between rodents and humans must be considered.

Somatosensory receptors in humans are located in the skin, muscles and joints from which information is projected towards the cortex. A topographic organization of the SSC is present in rodents and primates (Penfield and Boldrey, 1937). In rodents, somatosensory input is dominated by the input of

the facial vibrissae, with the somatotopic field representing the whiskers making up more than two-thirds of SSC (Paxinos and Franklin, 2019).

The equivalent peripheral receptor in humans would be the fingertips, that are each innervated by a comparable number of sensory neurons as the whiskers (Balasco et al., 2019). One obvious difference between fingertip touch and whisker touch is that rodents do not manipulate objects with their whiskers, but solely to sense texture, which in return leads to different mechanisms of sensing and coding for texture. In rodents the firing rate of neurons in S1BF differs between smooth and rough surfaces (Lottem and Azouz, 2009). In primates the different surface textures are transduced via rapidly adapting Pacinian corpuscles or slowly adapting mechanoreceptors (Connor and Johnson, 1992; Hollins and Bensmaïa, 2007). Anatomical organization of ascending somatosensory pathways is highly preserved throughout evolution, showing a similarity between primates and rodents (reviewed in Balasco et al., 2019).

Atypical sensory experiences and hyper-/ hyporeactivity in response to sensory stimuli are among the key symptoms of ASD (Balasco et al., 2019; Lauber et al., 2016). Several rodent ASD models show tactile hypersensitivity: Shank2 KO mice have impaired tactile perception (Ko et al., 2016) and mutations in Mecp2, Gabrb3, Shank3 and Fmr1, all being susceptibility genes in ASD, resulted in altered tactile discrimination, hypersensitivity to touch, and withdrawal to novel stimulations (Orefice et al., 2016; Schaffler et al., 2019). Deficits in social interaction and anxiety disorders are often accompanied by such tactile dysfunctions (Tuttle et al., 2016). Moreover, hyposensitivity was observed in rats exposed to VPA postnatally (Reynolds et al., 2012).

The constant flood of information to the sensory cortices requires precise filtering and integration before processing and transformation into an appropriate motor response. It has been reported that many symptoms seen in ASD are a response to an over- or under-reactive stimulation and disrupted sensory processing (Sinclair et al., 2017). Therefore, it could be hypothesized that impaired adaptation in cortical sensory circuits and early developmental

changes in S1BF may be a potential cause of sensory hypersensitivity and tactile defensiveness observed in several models of ASD (He et al., 2017).

5.3.1 Homeostatic plasticity of the AIS in S1BF

It has been shown that AIS morphology is directly correlated to intrinsic neuronal excitability (Jamann et al., 2018). Considering adaptations to altered network state in the context of homeostatic plasticity, sensory deprivation leads to elongation of the AIS and thus increased excitability (Jamann et al., 2021; Kuba, 2010). Overstimulation, either via sensory input *in vivo* (Jamann et al., 2021) or chronic depolarization *in vitro* (Grubb and Burrone, 2010) on the other hand leads to AIS shortening (in vivo) or relocation (in vitro) and reduced excitability.

One of the best studied systems in the context of cortical homeostatic plasticity during development and in the adult is the rodent whisker-to-barrel system. The development of whisking is tightly connected to the development of motor behavior and lack of function during early postnatal stages causes impairments in motor coordination and tactile behavior throughout the rest of the rodent life (Papaioannou et al., 2013; Sullivan et al., 2003). At P3, pups can respond to spontaneous whisker movements and passive deflections, helping them to orientate towards their mothers and littermates (Arakawa and Erzurumlu, 2015). Active exploration and palpation whisking does not start until the end of the second postnatal week (P12/13) (Akhmetshina et al., 2016), when the integration of tactile sensory information with sensorimotor processes results in motor performance. Whisking patterns increase until they reach their adult form at the end of the third postnatal week (Arakawa and Erzurumlu, 2015).

Following the timespan of the switch of synchronous and spatially confined spindle bursts caused by passive whisker deflection at P3 and the change towards a more desynchronized state at P12 (Khazipov et al., 2004), a gradual elongation of the AIS was observed in layer II/III and layer V in the VPA and the control group (Figure 14).

With the sudden onset of directed sensory input to the somatosensory cortex at P12 and the accompanying elevation of network activity, we find that AIS shorten (Figure 17). Several other developmental changes occur during the CP at end of the second postnatal week, causing a major restructuring of cortical connectivity (van der Bourg et al., 2017) and development of inter- and intracortical connections (Stern et al., 2001). Excitatory synapses between layer IV and layer II/III as well as the local connectivity of layer II/III neurons are strengthened through the effect of the ongoing whisker stimulation (Clem et al., 2008; Wen and Barth, 2011). As synaptic density and spine turnover increases, the intrinsic excitability in layer II/III neurons decreases (Lendvai et al., 2000; Maravall et al., 2004; Micheva and Beaulieu, 1996). Collectively, whisker-evoked responses and information processing is reduced in superficial layers II/III and IV but increased in deep layers V and VI (van der Bourg et al., 2017).

Overall, inhibition is elevated by the appearance of GABAergic synapses originating from chandelier cells (ChC), beginning to exert influence on the E/I balance in S1BF (Pan-Vazquez et al., 2020). It has been suggested that numerous neurodevelopmental disorders, such as autism, are associated with disturbances in the E/I balance, and that increase of the number and strength of inhibitory synapses is one of the responsible factors for balance shifts (Zhang et al., 2011). Mice with GABA receptor defects show impaired social and exploratory behavior similar to those reported in ASD (DeLorey et al., 2008).

We analyzed the total number of GABAergic synapses along the AIS in layer II/III of adult mice (> P45) and found no differences between both groups (Figure 18). If altered E/I balance and synaptic transmission has been recurrently implicated in several ASD models, then why were we unable to observe such alterations here?

One explanation for this could simply be the fact that the number of AIS that were analyzed (83 per group) was too small to depict a representative numbers of inhibitory synapses originating from ChC in S1BF. Expanding the analysis of those synapses could reveal possible effects that confirm the reported elevation of GABAergic inhibition. Next, the animals that were used where only adults of >P45 days of age. The CP for synaptic plasticity persists throughout

development, but eventually this time window closes (Jiang et al., 2007). It would be interesting to analyze the number of GABAergic synapses in younger animals to see if temporary changes during the CP could be found. Another methodological reason would be that immunohistochemical staining of the pre- and postsynapse are not sufficient enough to pick up subtle changes on molecular or functional level such as the number of vesicles released or changes of the postsynaptic excitatory Ca^{2+} -transients. And since AIS length did undergo significant length increase in layer V after VPA-exposure, it might be of greater interest to expand this type of analysis into layer V.

The analysis of apical dendrites of pyramidal cells in cortical layer II neurons revealed a higher density of spines in pyramidal cells in ASD, indicating defects in synaptic pruning (Piochon et al., 2016). It is likely that by only considering synapses along the AIS, changes at apical dendrites were not detected (Hutsler and Zhang, 2010).

Cortical neurons show the ability to structurally remodel their AIS corresponding to changes in sensory input, even throughout adulthood. This is generally believed to contribute to the dynamic maintenance of properly functioning neuronal networks (Engelhardt et al., 2019; Turrigiano, 2012). In several systems studied so far, AIS length seems to reach its optimum length at an adult time-point (Gutzmann et al., 2014; Jamann et al., 2021; Schlüter et al., 2017). In the present study, this process of AIS elongation and shortening was confirmed.

This distinct developmental pattern is suggested to result from the sudden onset of new sensory input (Jamann et al., 2018). Non-sensory areas do not respond in a similar manner. For example, the rat primary motor cortex (M1) lacks a sudden onset of input after birth, since pups start to move *in utero*. Consequently, M1 layers II/III and V show a continuous elongation of AIS (Benedetti et al., 2020). A similar developmental profile was previously published for the non-sensory cingulate cortex (Gutzmann et al., 2014).

Here, data indicate that AIS length development does not seem to be impacted by VPA-exposure since the hallmark length increase up to P15 and decrease in

adulthood (P45) are reminiscent of previously published maturation profiles (Gutzmann et al., 2014; Jamann et al., 2021). VPA-exposure was not disruptive enough to influence this distinct developmental pattern of mouse S1BF. The mice used in this study were held without any deprivation of sensory input and the exposure of VPA was only once during a very early embryonic age. The influence of sensory information or the deprivation of such during CPs possibly has a bigger impact on developmental length changes (Kuba, 2010) as the exposure with VPA long before the onset of CP.

5.3.2 Differences in layer-specific adaptation processes

Previous studies have provided evidence for a layer-specific neuronal and synaptic plasticity (Crair and Malenka, 1995; Rao and Daw, 2004). Long-term potentiation (LTP) and long-term depression (LTD) are forms of activity-dependent synaptic plasticity, crucial for the efficacy and constructive use of excitatory synaptic transmission. While they produce opposing effects on synaptic transmission, they are involved in learning and memory formation, sensory processing and motor coordination - and therefore have been implicated in the pathogenesis of neurodevelopmental disorders (Hansel, 2019). The regulation of LTD, especially presenting as deficits in spine pruning, is impaired in ASD and contributes to the already described E/I imbalance (Hutsler and Zhang, 2010; Piochon et al., 2016). This kind of synaptic plasticity proceeds sequentially through cortical layers, following the flow of incoming information, and diminishes early in layer IV, but persists throughout development in layer II/III (Jiang et al., 2007). While the CP for modifiable responses in layer IV closes very soon postnatally, this fact could help to explain why the CP of changes in layer II/III persist until later age stages. Synaptic plasticity and spine dynamics therefore seem to be primary features of supragranular layers, compared to infragranular layers (van der Bourg et al., 2017).

It has been implied that the dysregulation of synaptic signaling and the delay of the CP of synaptic plasticity in infragranular layers could be involved in causing

the ASD symptoms in the Fragile-X-model of autism (Harlow et al., 2010). Neuroligin-4 is a cell-adhesion protein that regulates synapse organization and function. Loss-of-function mutations of Neuroligin-4X are among the most common causes for the monogenetic development of ASD (Unichenko et al., 2018). Again, disrupted GABAergic transmission and shifts in E/I imbalance seem likely to be the underlying cause of the presentation of ASD symptoms in this model. *Unichenko et. al.*, showed that in ASD models, the incoming whisker-mediated sensory information to S1BF is not influenced, but rather the intracortical processing of information (Unichenko et al., 2018). This could help to understand why no AIS length changes in layer II/III were observed, whereas possible disruptions in intracortical processing could cause AIS shortening found in layer V (Figure 17). Our findings, indicating that AIS length decreases only in infragranular layers, also correlates with data published by *He and colleagues*. They could not find indications for exaggerated sensory-evoked firing in local networks nor a higher proportion of recruited neurons in layer II/III in S1BF after whisker-stimulation (He et al., 2017).

Although it has been reported that VPA-exposure suppresses the formation of inhibitory synapses in cultured cortical neurons (Kumamaru et al., 2014), the number of inhibitory synapses was unchanged in supragranular layers in the present study. So far, we did not investigate whether layer V synapses might show any changes in this regard. If those synaptic mechanisms might be involved in the VPA-model remains unclear for the moment and up to further investigation.

The fact that supra- and infragranular layers play different roles in adaptation processes could help to explain why we exclusively observed AIS length changes in layer V after VPA exposure, while AIS in layer II/III remain unchanged. Our results from patch-clamp recordings support this notion. Neither the active nor passive properties were significantly different between both groups. As the AIS length and its ion channel endowment are some of the significant modulators in neuronal excitability and no evidence of changes were found regarding those parameters, it was also expected to find no differences between both groups in the electrophysiological recordings.

5.3.3 The role of ankG in S1BF in the development of ASD

The main scaffolding protein of the AIS, ankG, is of great importance for the maintenance of the AIS, for AP generation and propagation (Akin et al., 2015; Pan et al., 2006; Zhou et al., 1998), and for synaptic transmission and spine maintenance (Smith et al., 2014; Tseng et al., 2015). AnkG has previously been linked to neurodevelopmental disorders such as schizophrenia, intellectual disability and ASD (Iqbal et al., 2013; Kaphzan et al., 2011; van der Werf et al., 2017). Children with mutations of ANK3, inhibiting the recruitment and binding of β IV-spectrin, exhibit several neurological defects, such as developmental delay and autistic features (Yang et al., 2019).

One of the most common ASD symptoms is increased anxiety, which is present in 40% of all patients diagnosed with ASD. Interestingly, ANK3 KO mice display similar anxiety behavior (van der Werf et al., 2017). The giant isoform of ankG (480kDa) interacts with the GABA_A-receptor-associated protein (GABA_ARAP) to stabilize GABA_A receptors at the surface of the soma and AIS of excitatory pyramidal neurons (Tseng et al., 2015). Abolishing ankG and disrupting the assembly of inhibitory synapses could contribute to the shifted E/I balance that has been reported in ASD (Nelson et al., 2018). It has been hypothesized that the level of cognitive impairment increases with decreasing levels of ankG protein in the brain (reviewed in (Huang and Rasband, 2018)).

With the shortening of AIS after VPA exposure, we hypothesized that a similar reduction in ankG protein expression might be observed in cortical samples of VPA-exposed mice. While the significant increase of ankG protein following AIS elongation during the second postnatal week has been reported (Gutzmann et al., 2014), we unexpectedly found that relative protein levels of all isoforms of ankG seemed to remain almost the same in both groups. We also did not find any differences between the relative protein levels of ankG between the VPA-exposed group and WT controls in neither of the time points at P3, P15 nor P45 (Figures 19-21). A comparable effect has been reported by *Alshammari and colleagues*, who also found that ankG levels of the PFC were comparable to those of WT mice in the BTBR T+Itpr3tf/J mouse model of autism (Alshammari

et al., 2019). It is important to keep in mind that due to anatomical limitations, whole cortical brain samples of early postnatal mice were used for analysis, which makes differentiation between the different areas of the neocortex impossible. AIS of other cortical areas do not undergo the tri-phasic developmental pattern that was observed in sensory cortices (Gutzmann et al., 2014; Jamann et al., 2021; Schlüter et al., 2017), but rather a monophasic elongation process (Benedetti et al., 2020). Possible change of the ankG levels in S1BF could be masked by the overall amount of ankG in neocortex contained in our samples. We also did not differentiate between supra- and infragranular layers. And importantly, ankG is also expressed at noR and the somatodendritic domain. Especially after the third postnatal week, a possible decrease of ankG could be masked by the increase of nodal ankG in lower levels (Gutzmann et al., 2014). Further studies are necessary to determine the effect of VPA-exposure to the expression profiles of axonal ankG and draw conclusions about the role that ankyrins in this disease phenotype.

5.4 The effect of VPA on neuronal excitability

5.4.1 Implications for the involvement of ion-channels in the disease pathomechanism

At P15, the level of sodium channel expression was increased in the VPA group (Figure 20). The shape of the AP is primarily influenced by the activation and inactivation kinetics of K_v and Na_v channels located along the AIS (Kole et al., 2007; Kole et al., 2008). Na_v channels are not exclusively located at the AIS, but also at the somatodendritic domain, noR and dendritic regions, although the Na^+ current density is significantly higher at the AIS (with a ratio of 1:34 compared to the soma and up to 50fold compared to the complete somatodendritic domain) (Hu et al., 2009; Kole and Stuart, 2012; Pal et al., 2015).

As Na_v channels play a critical role in the generation of AP and intrinsic membrane properties, enhanced expression could have serious consequences regarding the excitability of the cell. Recruitment of Na_v channels to the AIS is therefore followed by an increase in neuronal excitability (Kuba and Ohmori, 2009).

In other mouse models of ASD, the expression of several Nav channels was significantly increased as measured by Western blot studies and high-resolution confocal microscopy (Alshammari et al., 2019; Kaphzan et al., 2011). Interestingly, the expression of Nav1.6 and Nav1.2 was increased at the AIS but also at the soma, suggesting alterations of both AP firing and backpropagation. Additionally, Nav1.1 expression was also increased, suggesting that the inhibitory current is also altered (Alshammari et al., 2019). In the Western blot analysis of this thesis, anti-panNav was used, which recognizes all Nav channels. By using this antibody, we can only speculate about the implications of the overall increase of Nav expression in the circuit. Because of their widespread distribution along neurons and the many different functions of Nav channel subtypes, it is challenging to draw conclusions from higher expression levels of panNav to specific functional changes (Figures 19-21).

Due to the high concentration of Nav channels at the AIS, small changes in the expression patterns could change AP properties. If the overexpression of functioning Nav1.6 channels at the AIS was indeed taking place, this could lead to a reduction in voltage threshold, and thus higher excitability. However, no differences regarding voltage threshold were observed in this study (Figure 23). It is important to mention that increased expression may not automatically indicate that a higher level of excitation is occurring. Rather, this could be a compensatory mechanism due to lack of function of the Nav channels.

Future studies should aim to distinguish alterations in the distribution of the different isoforms and investigate possible effects on neuronal excitability. Apart from all the uncertainties, several different mutations of sodium channel subtype encoding genes have been associated with ASD phenotypes (Ben-Shalom et al., 2017; Schmunk and Gargus, 2013; Weiss et al., 2003), bringing Nav channels into the context of the one common denominator of the disease pathomechanism: influencing the imbalance in the E/I ratio (reviewed in (Schmunk and Gargus, 2013).

After the evaluation of these results, and in light of the fact that mutations and dysfunctions of Kv channels have been associated with ASD in the past (Indumathy et al., 2021), AP properties became a center of attention in the patch-clamp recordings that were conducted to gain information about possible

functional effects of VPA-exposure. Interestingly, we observed significant changes to AP shape and kinetics (Figure 24) in layer V of S1BF. AP half width was significantly reduced in VPA-exposed mice, indicating a faster depolarization and repolarization phase in VPA-exposed neurons. As outlined previously, the AP waveform is dependent on activation kinetics of K_v s, especially K_v1 (Bean, 2007). Since blockage of K_v1 channels caused a broadening of APs (Kole et al., 2007), it would be interesting to investigate if a recruitment of K_v channels to the AIS, resulting in a higher channel density, would show the opposing effects that we observed after VPA-exposure.

5.5 The basal ganglia and their involvement in the development of the ASD phenotype

Given the broad spectrum of important functions in motor planning, action selection and reward-guided learning (Burke et al., 2017; Burton et al., 2015), it is not surprising that striatal dysfunctions constitute a variety of pathophysiological mechanisms underlying neuropsychological disorders, such as ASD. Alterations in excitatory and inhibitory synaptic transmission in the ventral and dorsal striatum have been implicated in different mouse models of autism (Fuccillo, 2016).

The AIS and its plasticity in striatal dopaminergic neurons has not been investigated so far. Generally, the phasic firing of dopaminergic neurons of the basal ganglia encodes for behaviorally relevant stimuli (Canavier et al., 2016). As in cortical neurons, the AIS is the key determinant for firing rate in these neurons and the firing rate itself is dependent on many factors including intrinsic ionic conductance, level of synaptic input, and the morphology of the somatodendritic compartment (Canavier et al., 2016; Jang et al., 2014). Computational modeling studies showed that the spontaneous firing rate increased with AIS length and is the causal determinant for the firing rate in dopaminergic neurons (Meza et al., 2018).

We set out to investigate whether AIS showed signs of structural remodeling in the ventral and dorsal striatum after VPA-exposure.

Striatal AIS length was analyzed in juvenile (P15) and adult wildtype control mice (P45). Interestingly, even under control conditions, striatal AIS are clearly shorter than cortical AIS. While AIS of layer II/III and layer V of S1BF displayed a medium length of at least 30 μm or longer at the age of P15, the medium length of AIS in the striatum was just around 22 μm . This would be approximately the size of cortical AIS at very early postnatal stages. The shape and arrangement of striatal AIS also shows differences compared to cortical AIS: in the cortex, AIS are oriented perpendicular to the pial surface, presenting almost parallel to one another in coronal sections (e.g. Figure 15 and 16). Even at early postnatal stages, where AIS present a more corkscrew-like shape, they still appear in this orientation (Figure 15 and 16). In the striatum, no specific orientation of AIS was found. AIS are “cluttered”, and three-dimensional folded, making it more complicated to identify single AIS and their originating soma. This is of course due to the fact that the mouse striatum is not a histologically “layered” structure. The length difference between SPN and cortical pyramidal neurons is also most likely due to soma size. As shown, AIS scale with somatodendritic geometry (Kole & Brette 2018, Goethals & Brette, 2020) and therefore, shorter AIS were expected for a cell population that is smaller in somatic diameter.

Based on the significant AIS length decrease in layer V pyramidal neurons in VPA-exposed mice, we hypothesized that this shortening – if an indication of increased excitability in cortical networks - would elicit a subsequent effect on AIS length in downstream pathways. AIS length was therefore expected to be increased in the DLS. Interestingly, AIS length in striatum at P15 was unchanged between both groups and also showed similar length distribution patterns (Figure 26). However, in the adult samples, AIS length of the VPA group were significantly longer compared to controls (Figure 26). It is tempting to speculate that the decreased excitability of neurons with shorter AIS in layer V of S1BF causes opposing effects in the striatum. Here, AIS receiving less input would consequently elongate in order to maintain their optimum firing rate.

In addition to overall AIS length analysis, the analysis of length distribution patterns showed interesting differences between the groups: AIS of controls concentrated more towards shorter lengths, while length distribution in the VPA group was heterogeneously distributed. In this context, it would be interesting to analyze the soma-to-AIS-distance and to confirm the negative correlation of the firing frequency that has been reported previously (Goncalves et al., 2017).

Since the length changes observed in striatal AIS were only small, it was not surprising that no significant differences in the immunoblot analysis of ankG or β IV-spectrin could be observed. Again, both proteins are abundantly expressed also in striatal cell populations and subtle changes could simply be masked or remain below the detection threshold of the assay.

VPA-exposure has resulted in significant effects on AIS geometry in different regions of the cortico-striatal circuit (Figure 32). It seems, as if the somatosensory input onto layer II/III is not altered, so neurons don't have to adapt to changes of excitability. This is according to publications by other groups, showing that sensory input to the cortex is not altered, but rather the intracortical connections (Unichenko et al., 2018). Therefore, the possible effects of VPA on pre- and postsynaptic plasticity and transmitter release could contribute changes of the E/I balance and result in shortening of the AIS in layer V (Gąssowska-Dobrowolska et al., 2020). Alteration in layer V AP properties could have an effect on the striatum, however, one has to consider that the striatum also receives input from other regions such as the thalamus, amygdala or hippocampus. The changes of AIS length in the DLS can therefore not exclusively be ascribed to the influence of altered cortical processing. Further studies have to be carried out to expand on the knowledge about how VPA-induced modifications in other brain areas could contribute to altered AIS length in the DLS.

Figure 32: Synopsis of the influence of VPA on S1BF and the striatum of rodents

A: In the control group, thalamocortical circuits are precisely coordinated, and the ratio of excitation and inhibition is balanced. **B:** In the VPA-exposed group, AIS length of layer II/III neurons showed no difference compared to controls. Alterations of pre- and postsynaptic function, as well as in ion channel function and number results in increased excitation levels, which causes neurons of layer V to shorten. Decreased signals from layer V to the DLS cause a reflective elongation of the AIS, ultimately resulting in a disbalance of excitation and inhibition that contributes to the presentation of ASD symptoms.

5.6 Influences of FOXP1 haploinsufficiency on striatal circuits

5.6.1 FOXP1^{+/-} impacts AIS morphology

FOXP1 is involved in transcriptional processes during striatal neurogenesis (Anderson et al., 2020). Disruptions of this pathway might explain possible anatomical changes in the basal ganglia. Brain-specific FOXP1 deletion has been reported to show gross morphological defects, with a reduction of total striatal area throughout development in rodent basal ganglia (Bacon et al., 2015). To investigate if FOXP^{+/-} has similar effects on striatal morphology, we performed TH immunohistochemistry followed by the analysis of total striatal area. Our data shows that heterozygous deletion of FOXP1 does not lead to the significant anatomical aberrations seen in the brain-specific FOXP1 knock-out (Figure 29).

AIS length analysis of striatal samples of FOXP1^{+/-} and controls showed that the average AIS length in striatal samples is comparable to the length measured in the VPA-model and its controls, presenting a medium length of approximately 22 μm (Figure 30). Contrary to what was detected in the VPA-induced model, AIS in the DLS were just slightly, but significantly shorter compared to wildtype controls in the case of the FOXP1^{+/-} model. AIS of the DMS on the other hand were not affected and showed no difference between both groups. Shorter AIS, as a result of an overstimulated dopaminergic circuit in the DLS with its inputs from primary motor and somatosensory cortices, could present a possible explanation for altered motor behavior and repetitive movements that were described for this model (Lee et al., 2018). Similar to our observations in the VPA model, structural differences in AIS length were only small, and were not seen in immunoblot analysis of ankG protein expression. Due to methodological limitations, whole brain samples were used for this analysis. FOXP1 is distributed not only in the striatum, but also in other cortical areas. Influences of FOXP1 haploinsufficiency on AIS morphology and on ankG expression levels might be hidden under the global effects and total amount of ankG in the brain.

Protein expression of voltage gated sodium and potassium channels were significantly reduced in FOXP1^{+/-} mice (Figure 31). This could present a more

significant effect on neuronal excitability as changes in voltage-gated ion channels have a large impact on AP properties (Kole et al., 2007). As outlined in the Introduction (2.4.3) and in section 5.4.1, K_V are critical for stabilizing the resting membrane potential, ensuring a high availability of Na_V channels, and modulation the waveform of the AP (Battfeld et al., 2014). Na_V are critical for AP initiation and backpropagation (Hu et al., 2009). Interestingly, mutations of K_V channels are associated with neurodevelopmental disorders in humans (Li et al., 2020). Intriguingly, heterozygous male mice showed significantly pronounced symptoms, which is of special interest in the context of the sex differences observed in ASD. The heterozygous loss of $Kv7.2$ induced repetitive movements such as increased marble burying and a decrease of social interest (Kim et al., 2020). Reduction of K_V protein expression could show the same effects as heterozygous deletion: namely, the development of autism-typical behaviors.

Therefore, to further elucidate the impact of the observed changes in VGSC expression, electrophysiological recordings should be performed in future studies.

5.7 ASD and the gender bias?

The striking difference in the number of males and females diagnosed with ASD has become the center of attention and discussion. A systematic review and meta-analysis of over 50 studies conclude the male-to-female ratio to almost 3:1 (Loomes et al., 2017). Even higher ratios have been reported in the past, especially in Asperger's syndrome (Fombonne, 2012). It has been suggested that diagnostic difficulties and protective mechanisms of the female sex might contribute to this gender bias (Kirkovski et al., 2013; Robinson et al., 2013). Our current understanding of factors that contribute to the differences that emerge in females and males are limited, and genetic and neuroanatomical differences have not been studied to a great extent (reviewed in Jeon et al., 2018).

Under these circumstances, it seemed obvious to separate our results by gender. The effect of AIS shortening in the striatum of $FOXP1^{+/-}$ mice was

pronounced in males (Figure 30). AIS of the DLS in male mice were significantly shorter compared to male WT controls. When comparing both groups of female mice, no difference in AIS length could be observed. Some form of hyperexcitability in male striatal circuits – here indicated by AIS shortening – could help to explain why the behavioral phenotypes are found to be more severe and more clearly presented in males than females (Kirkovski et al., 2013). It has to be kept in mind though that the total number of animals used in this study was quite small ($n=12$). To further underline this interesting finding, future studies should increase the number of experimental animals of both genders.

Figure 33: Synopsis of the influences of FOXP1^{+/-} on striatal circuits

A: In FOXP1 WT mice, the ratio of excitation and inhibition is balanced. B: In FOXP1^{+/-} mice increased excitability of upstream pathways could be causative for the shortening of AIS length and channel downregulation, in order to reduce the level of excitation. AIS of FOXP1^{+/-} males showed a pronounced affect in comparison to FOXP1^{+/-} females. This could help to explain the gender bias observed in the FOXP1^{+/-} model of autism and ASD in general. Functional consequences of this length decrease, and channel reduction remain unclear and could be the subject of further studies.

5.8 Similarities and differences between the two ASD models

One aim of this study was to elucidate possible commonalities between two very different mouse models of autism that could help to uncover common morphological changes underlying the pathophysiology of ASD and also serve to validate animal models.

Interestingly, we found that FOXP1 protein expression was slightly reduced in striatum of VPA-exposed mice. Reduced levels of FOXP1, either triggered by heterozygous deletion of FOXP1 or the exposure with VPA could therefore present one possible commonality between the two ASD-models investigated in this study. Mutations of the transcription factor FOXP1, that is crucial for global cognitive development and gross motor function, have been linked to neurodevelopmental disorders such as ASD and Intellectual Disability (Ayhan and Konopka, 2019; Bowers and Konopka, 2012; Co et al., 2020; Siper et al., 2017). Apart from various other regions, FOXP1 is strongly expressed in cortical layer V (Anderson et al., 2020). If one mechanism of VPA would be the reduction of FOXP1 expression in cortical layers, this could explain why AIS length changes in layer V appeared more clearly. Cortical neurons of individuals with mutations in FOXP1 showed altered dendritic morphology (Li et al., 2018), a mechanism that was also indicated as a contributing factor to the altered E/I imbalance in the VPA model of autism (Gogolla et al., 2009).

AIS in circuits of the DLS did also seem to be altered in both models: In case of the VPA model, a slight elongation was detected, whereas in FOXP1^{+/-}, a significant reduction of AIS length was seen. Both effects might be implications for altered network states and E/I imbalances in circuits upstream of the striatum, e.g. S1BF. Of note, the striatum does not only receive input from S1BF, but from other sensory cortices, the motor cortex, associative areas, insular cortices and the thalamus (Burke et al., 2017; Fuccillo, 2016); Figure 9). Its role lies in the integration of all incoming information for action selection and initiate adequate behavioral responses (Fuccillo, 2016). Disturbances in any of those regions could therefore contribute to the morphological changes that were observed in DLS and cannot be ascribed to input from S1BF alone.

Unfortunately, cortical samples of FOXP1^{+/-} mice and samples of younger mice were not available to us during the course of this study. Whether FOXP1 has an effect on the morphology of cortical AIS in supra- or infragranular layers, and if developmental processes are altered in this ASD model therefore remains unclear at this point and could present the basis of further studies.

6 SUMMARY

The axon initial segment (AIS) constitutes the site of action potential generation in neurons and thus plays an important role in the regulation of cellular excitability and neuronal circuit function. Recent studies have shown that the AIS can undergo structural and functional plasticity both during development and in the adult. Changes can include the remodeling of length and position, both dependent on the network state. It has been hypothesized that an imbalance of excitation and inhibition in the fronto-striatal circuitry is involved in the development of ASD phenotypes. The AIS, as a dynamic regulator of intrinsic excitability and neuronal circuit function might contribute to this imbalance.

VPA is an antiepileptic drug that is known to be highly teratogenic and has severe effects, including the development of autistic features, on the unborn child when taken during pregnancy. Similar effects after *in utero* exposure could be found in rodent models. Analogies in brain structure and similarities of behavioral patterns between VPA exposed rodents and patients with ASD lead to the conclusion that the VPA-model of autism is suitable to investigate changes to neuronal circuits in the autistic brain.

The transcription factor forkhead box protein 1 (FOXP1) has been shown to regulate neuronal excitability in striatal spiny projection neurons (SPN) and has been identified as a risk factor in the development of ASD. FOXP1 knockout (FOXP1^{-/-}) mice show typical ASD features such as restrictive and repetitive patterns of behavioral output, deficits in learning, memory and social interaction. The question, if ASD-typical neurodevelopmental changes and behavioral patterns could be traced back to alterations in AIS morphology have not been addressed so far. Thus, this thesis was carried out to analyze possible alterations of AIS development and intrinsic neuronal excitability and find possible anatomical correlations with the ASD phenotype.

Using a combination of immunofluorescent staining, confocal microscopy and 3D reconstruction, Western blot analysis and electrophysiological recordings, the aim was to detect a broad spectrum of anatomical and functional changes corresponding to ASD phenotypes at the single neuron level. The VPA and

FOXP1^{+/-} models were chosen to evaluate commonalities and differences between two different mouse models of ASD.

AIS plasticity was analyzed in different areas along the pathway of the fronto-striatal circuit in the VPA-model. Firstly, in layer II/III of S1BF no changes to AIS length or number of inhibitory synapses were detected, indicating that the sensory input to cortical regions might not be affected by VPA exposure. However, several mechanisms could contribute to the shortening of AIS length that was observed in layer V throughout development. Alterations of synaptic transmission and ion channel constitution could result in higher neuronal activity and lead to shortening of AIS length in layer V, accompanied with changes in intrinsic firing properties of the neurons, which were detected by whole-cell patch-clamp recordings. Interestingly, while infragranular AIS showed a length decrease, medium spiny neurons of the dorsolateral striatum (DLS) showed the opposite, an increase in AIS length, possibly indicating a homeostatic mechanism of AIS length remodeling.

Of note, in adult FOXP1^{+/-} mice, AIS were elongated in the DLS compared to the control group. This morphological change was accompanied by a downregulation of ion channel protein expression. Possible commonalities between the two different models could be morphological changes in the DLS of rodents, leading to the presentation of ASD-typical behavioral pattern such as repetitive movements.

Taken together, the data are the first to indicate that AIS length changes in infragranular pyramidal neurons of S1BF and/or medium spiny neurons of the DLS could contribute to the phenotype observed in these two distinct and commonly-used murine models of ASD, possibly by exacerbating an already existing imbalance of excitation and inhibition in neuronal networks. Functional data obtained by patch-clamp recordings further underscore the fact that ASD-neurons possibly restructure their ion channel architecture and thus undergo significant changes of their own intrinsic excitability, thereby affecting the surrounding network. Moreover, data of the current thesis also provides some evidence for a gender-dependent phenotype in line with observations from human cases.

Image Processing	IMARIS V9.0	Bitplane, Zürich, Switzerland

9 OWN PUBLICATIONS

Parts of the objective, methods, results and discussion as well as some of the figures and statistics provided in this thesis have been published in:

9.1 Publications in peer-reviewed journals

Jamann, N.*, **Jordan, M.***, and Engelhardt, M. (2018). Activity-dependent axonal plasticity in sensory systems. *Neuroscience* 368, 268-282.

* equally contributing authors

9.2 Conference Publications and Abstracts

Poster:

Jordan M., Anderson A., Corcelli C., Schultz C., Konopka G., Engelhardt M.: *Structural Remodeling of the axon initial segment in a mouse model of autism.* FENS Forum, Annual Meeting of the Federation of European Neuroscience Societies, Berlin 07/2018

Poster:

Jordan M., Corcelli C., Vorwald S., Jamann N., Schultz C., Engelhardt M.: *Structural and functional plasticity of the axon initial segment in a mouse model of autism.* Neuroscience 2018, Annunial Meeting of the Society for Neuroscience, San Diego, CA, USA 11/2018

10 CURRICULUM VITAE

Personal Details

Name	Merryn Paula Jordan
Date of Birth	21.10.1993
Place of Birth	Weingarten, Germany
Nationality	German

Education

2012 – 2020	Medical Studies, Medical Faculty Mannheim, University Heidelberg
11/2020	Medical Exam, Grade 2.0
11/2020	Third state examination
04/2019	Second state examination
08/2014	First state examination
2010 – 2012	Theodor-Heuss-Gymnasium, Heilbronn
07/2012	Abitur, Grade 1.5
2008 – 2010	Robert-Mayer-Gymnasium, Heilbronn
2003 – 2008	Schiller-Gymnasium, Offenburg
1999 – 2003	Lindenhofschule, Massenbachhausen

Scholarships and Awards

01/18 – 12/18	Doctoral Fellow, Medical Faculty Mannheim, University Heidelberg
11/2019	Travel Grant, German Academic Exchange Service (DAAD), SfN Meeting, San Diego, CA, USA

- 03/2018 Travel Grant, German Neuroscience Society, FENS Forum of Neuroscience
- 07/2012 Theodor-Heuss-Gymnasium, Heilbronn
Award for extraordinary social commitment

Professional Experience and Voluntary Work

- 2014 – 2018 Medical Faculty Mannheim, Heidelberg University,
Student Assistant/ Tutor for Physiology, Anatomy and Histology
- 2014 - 2016 Medical Faculty Mannheim, Heidelberg University,
Mentoring Program, Senior Mentor
- 2013 - 2017 IFMSA (International Federation of Medical Students' Association), SCORA (Standing Committee on Reproductive Health including AIDS),
Active Member and Boardmember

11 ACKNOWLEDGEMENTS

Maren, I am so thankful that you were my supervisor and mentor for this thesis. Your encouragement, diligence, and thorough working attitude was inspirational to me with this project. You were always there to provide answers, explanations, input, justified criticism and ironic comments, and never hesitated to help with any request. Taking me to SfN and the FENS meetings were certainly highlights of the last years. I really appreciate those opportunities and all the work you put into this thesis.

Thank you to Prof. Dr. med. Christian Schultz, for providing the opportunity and equipment to conduct all the experiments and work on this project. Kitty, for your organizational support and for your encouraging words.

I want to thank the Medical Faculty Mannheim, for receiving the “Promotionsstipendium”, that gave me the opportunity to focus thoroughly on the work for this thesis.

Silke und Corinna, I really appreciate the time you took to teach me everything I needed to know, taking care of the animals and helping me to perform the experiments. I would certainly be still sitting at the bench doing western blots and stainings, if it wasn't for your help and expertise.

Thanks to the other students in the lab, I was a pleasure being part of the group where everyone supporting each other whenever possible. And it definitely was a lot more fun, knowing that almost always, there would be one of you keeping me company when I was at the lab. Jonathan, thanks for your help with the synapse analysis, Johannes for your tech support and the AISuite, which saved everyone a great deal of time. Caro and Nadja for getting on with the VPA project, I am very curious about where this will go.

Special thanks go to Dominik, for your endless patience and problem-solving skills. And, of course, Nora, for designing the VPA-project with me, passing on all your knowledge and tips, being available to answer questions and give feedback almost at any time and stepping up to do the recordings when I

couldn't. The patch-clamp recordings were a key element in this thesis, and they wouldn't have been possible without you both.

To "Das Dorf", you exceptional group of people, filled those years with unforgettable memories. I am so glad that we've got to know each other.

Fabi, for being there and having my back. I can't wait to see what the future holds for us next.

And most importantly, I want to thank my parents for their continuous support through 8 years of studies. You always trusted in my decisions and never hesitated to financially and morally support whatever plan I came up with next. I know that you are proud of me, and this is why I am too.
